

INFORMATION TO USERS

This manuscript has been reproduced from the microfilm master. UMI films the text directly from the original or copy submitted. Thus, some thesis and dissertation copies are in typewriter face, while others may be from any type of computer printer.

The quality of this reproduction is dependent upon the quality of the copy submitted. Broken or indistinct print, colored or poor quality illustrations and photographs, print bleedthrough, substandard margins, and improper alignment can adversely affect reproduction.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyright material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand corner and continuing from left to right in equal sections with small overlaps. Each original is also photographed in one exposure and is included in reduced form at the back of the book.

Photographs included in the original manuscript have been reproduced xerographically in this copy. Higher quality 6" x 9" black and white photographic prints are available for any photographs or illustrations appearing in this copy for an additional charge. Contact UMI directly to order.

Combining Analyses, Combining Optimizations

Clifford Noel Click, Jr.

Abstract

This thesis presents a framework for describing optimizations. It shows how to combine two such frameworks and how to reason about the properties of the resulting framework. The structure of the framework provides insight into when a combination yields better results. Also presented is a simple iterative algorithm for solving these frameworks. A framework is shown that combines Constant Propagation, Unreachable Code Elimination, Global Congruence Finding and Global Value Numbering. For these optimizations, the iterative algorithm runs in $O(n^2)$ time.

This thesis then presents an $O(n \log n)$ algorithm for combining the same optimizations. This technique also finds many of the common subexpressions found by Partial Redundancy Elimination. However, it requires a global code motion pass to make the optimized code correct, also presented. The global code motion algorithm removes some Partially Dead Code as a side-effect. An implementation demonstrates that the algorithm has shorter compile times than repeated passes of the separate optimizations while producing run-time speedups of 4% – 7%.

While global analyses are stronger, peephole analyses can be unexpectedly powerful. This thesis demonstrates parse-time peephole optimizations that find more than 95% of the constants and common subexpressions found by the best combined analysis. Finding constants and common subexpressions while parsing reduces peak intermediate representation size. This speeds up the later global analyses, reducing total compilation time by 10%. In conjunction with global code motion, these peephole optimizations generate excellent code very quickly, a useful feature for compilers that stress compilation speed over code quality.

Acknowledgments

First and foremost I wish to thank Melanie, my wife of six years. Her courage and strength (and level-headedness!) has kept me plowing ahead. I must also mention Karen, my daughter of 1 year, whose bright smiles lighten my days. I wish to thank Keith Cooper, my advisor, for being tolerant of my wild ideas. His worldly views helped me keep track of what is important in computer science, and helped me to distinguish between the style and the substance of my research. I also thank Mark Krentel and his “Big, Bad, Counter-Example Machine” for helping me with the devilish algorithmic details, Bob Bixby for his large numerical C codes, and Linda Torczon for her patience.

While there are many other people in the Rice community I wish to thank, a few stand out. Michael Paleczny has been an invaluable research partner. Many of the ideas presented here were first fleshed out between us as we sat beneath the oak trees. I hope that we can continue to work (and publish) together. Chris Vick has been a great sounding board for ideas, playing devil’s advocate with relish. Without Preston Briggs and the rest of the Massively Scalar Compiler Group (Tim Harvey, Rob Shillingsburg, Taylor Simpson, Lisa Thomas and Linda Torczon) this research would never have happened. Lorie Liebrock and Jerry Roth have been solid friends and fellow students through it all.

Last I would like to thank Rice University and the cast of thousands that make Rice such a wonderful place to learn. This research has been funded by ARPA through ONR grant N00014-91-J-1989.

Preface

My first introduction to compiler writing occurred in 1978 when, at the prompting of a Byte magazine article, I implemented a tiny Pascal compiler. The compiler ran in 4K, took two passes and included a peephole optimizer. While it was many years before I would write another compiler, I still feel that compilers are “neat” programs.

In 1991, when I began studying compilers in earnest, I found that many forms of program analysis share a common theme. In most data-flow analysis frameworks, program variables are initialized to a special value, T . This special value represents an optimistic assumption in the analysis. The analysis must do further work to prove the correctness of the T choice. When I began my work on combining analyses, I used my intuition of the optimistic assumption to guide me. It was clear that constant propagation used the optimistic assumption and that I could formulate unreachable code elimination as an optimistic data-flow framework. But the combination, called conditional constant propagation [49], was strictly stronger. In essence, Wegman and Zadeck used the optimistic assumption between two analyses as well as within each separate analysis. This work states this intuition in a rigorous mathematical way, and then uses the mathematical formalism to derive a framework for combining analyses. The framework is instantiated by combining conditional constant propagation, global value numbering [2, 37, 36, 18], and many techniques from hash table based value numbering optimizations [12, 13].

Chapter 1

Introduction

This thesis is about *optimizing compilers*. Optimizing compilers have existed since the 1950s, and have undergone steady, gradual improvement [3]. This thesis discusses the compilation process and provides techniques for improving the code produced as well as the speed of the compiler.

1.1 Background

Computers are machines; they follow their instructions precisely. Writing precisely correct instructions is hard. People are fallible; programmers have difficulty understanding large programs; and computers require a tremendous number of very limited instructions. Therefore, programmers write programs in *high-level languages*, languages more easily understood by a human. Computers do not understand high-level languages. They require *compilers* to translate high-level languages down to the very low-level machine language they do understand.

This thesis is about *optimizing compilers*. Translation from a high-level to a low-level language presents the compiler with myriad choices. An optimizing compiler tries to select a translation that makes reasonable use of machine resources. Early optimizing compilers helped bring about the acceptance of high-level languages by generating low-level code that was close to what an experienced programmer might generate. Indeed, the first FORTRAN compiler surprised programmers with the quality of code it generated [3].

1.2 Compiler Optimizations

One obvious method for improving the translated code is to look for code fragments with common patterns and replace them with more efficient code fragments. These are called *peephole* optimizations because the compiler looks through a “peephole”, a very small window, into the code [16, 42, 17, 23, 24]. However, peephole optimizations are limited by their local view of the code. A stronger method involves *global analysis*, in which the compiler first inspects the entire program before making changes.

A common global analysis is called *data-flow analysis*, in which the compiler studies the flow of data around a program [12, 29, 30, 31, 45, 1]. The first data-flow analyses carried bit vectors to every part of the program, modified the bits, and moved them on to the next section. Bit-vector data-flow analyses require several passes over the program to encode the facts they are discovering in the bits. Since different analyses give different meanings to the bits, the compiler requires many passes to extract all the desired knowledge. Thus bit-vector analysis runs a little slower and uses more memory than peephole analysis. However, its global view allows the compiler to generate better code.

Data-flow analysis has moved beyond bit vectors to more complex sets [33]. *Constant propagation* is a data-flow analysis in which the compiler attempts to discover which variables have known constant values in every program execution. In the code below, the compiler tries to determine whether x is a constant.

```

x := 1;
do {
  x := 2 - x;
  ...
} while ( ... );

```

On the first line, x is clearly 1. On the next line, the value for x flowing around the loop backedge depends on any assignments to x in the loop body. The compiler can (pessimistically) assume that the loop body will modify x to an arbitrary value, causing x 's value to be unknown at the loop top. When the compiler detects the assignment in this loop body, the value assigned to x is unknown; 2 minus any integer can be any integer. However, if the loop body does not further modify x , then the pessimistic assumption is not ideal. Since 2 minus 1 is 1, x is clearly constant. Instead, the compiler can (optimisti-

cally) assume that x remains unchanged in the loop body, so that x 's value on the loop backedge is 1. When the compiler inspects the loop body, it finds that the assignment does not change x . The compiler's assumption is justified; x is known to be constant.

In the modern version of constant propagation, the compiler makes the *optimistic assumption*. [49] It assumes variables are constant and then tries to prove that assumption. If it cannot, it falls back to the more pessimistic truth (*i.e.*, the variable was not a constant).

The results of analyses can affect each other. Knowing that a value is constant may let the compiler remove some unreachable code, allowing it to find more constants. In the code below, after the compiler first runs constant propagation, it knows x is always 1, but the final value of y is unknown. However, the compiler does know that the test is always false, so the test and the unreachable code " $y := 3$ " can be removed. A second run of constant propagation will correctly discover that y is always 2.

```
x := 1;
y := 2;
if( x ≠ 1 )
    y := 3;
```

This occurs because the two optimizations, *constant propagation* and *unreachable code elimination*, interact; they exhibit a *phase-ordering* problem [1]. The two separate analyses make use of the optimistic assumption within themselves, but not between themselves. For example, constant propagation assumes all code is reachable; it never assumes code is unreachable. Unreachable code elimination assumes that all tests are not constants; it never assumes that some expression may compute a constant (it does understand the two constant tests "if TRUE" and "if FALSE"). Unfortunately, these optimizations do not both make their optimistic assumptions at the same time. In *Conditional Constant Propagation* (CCP), both assumptions are made at the same time [49]. CCP combines these two analyses optimistically; facts that simultaneously require both optimistic assumptions are found. The combined analysis replaces both constant propagation and unreachable code elimination. CCP is stronger than repeating the separate analyses any number of times; it removes the phase-ordering problem between them.

Part of my work concerns combining optimizations. This thesis discusses under what circumstances an optimization can be described with a *monotone analysis framework*. Two analyses described with such frameworks can be combined. This thesis also discusses situations in which it is profitable to combine such optimizations and provides a simple technique for solving the combined optimization.

1.3 Intermediate Representations

Compilers do not work directly on the high-level program text that people write. They read it once and convert it to a form more suitable for a program to work with (after all, compilers are just programs). This internal form is called an *intermediate representation*, because it lies between what the programmer wrote and what the machine understands. The nature of the intermediate representation affects the speed and power of the compiler.

A common intermediate representation in use today is the *Control Flow Graph* (CFG) with basic blocks of *quads* [1]. A quad is a simple 3-address operator. It looks like an expression of the form “ $a := b + c$ ”. The four pieces include the two input variables b and c , the add operator, and the output variable a . Each quad represents the amount of work a single machine instruction can do. A basic block is a section of code with no control flow. The compiler converts the code in the basic block from the high-level language to quads. A single high-level language statement may translate to many quads. The CFG is a directed graph. The vertices represent basic blocks and the edges represent possible directions of program control flow.

Quads are a powerful and flexible program representation. However, they have a flaw: they record names instead of values. When the compiler wishes to determine if a is a constant in “ $a := b + c$ ”, it must first determine if b and c are constants. The name b does not tell the compiler what the program last assigned to b or where that last assignment occurred. The compiler must carry information about assignments to b forward to all possible uses of b . It must do the same for c , and for all variables. This requires carrying vectors of information around, even to assignments that do not use b .

A better method is to record *use-def chains* with each quad [32, 1]. Use-def chains represent quick pointers from uses of a variable (like b) to the set of its last definitions. The compiler can now quickly determine what happened to b in the instructions before “ $a := b + c$ ” without carrying a large vector around. Use-def chains allow the formalism of a number of different data-flow analyses with a single framework. As long as there is only a single definition that can reach the quad, there is only one use-def chain for b . However, many definitions can reach the quad, each along a different path in the CFG. This requires many use-def chains for b in just this one quad. When deciding what happened to b , the compiler must merge the information from each use-def chain.

Instead of merging information about b just before every use of b , the compiler can merge the information at points where different definitions of b meet. This leads to *Static Single Assignment* (SSA) form, so called because each variable is assigned only once in the program text [15]. Because each variable is assigned only once, we only need one use-def chain per use of a variable. However, building SSA form is not trivial; programmers assign to the same variable many times. The compiler must rename the target variable in each assignment to a new name; it must also rename the uses to be consistent with the new names. Any time two CFG paths meet, the compiler needs a new name, even when no assignment is evident. In the code below, the compiler renames x in the first assignment to x_0 and x in the second assignment to x_1 . In the use of x in the third statement, neither of the names x_0 nor x_1 is correct. The compiler inserts a ϕ -function assignment to x_2 and renames the use to x_2 .¹

if(...) $x := 1$;	if(...) $x_0 := 1$;
else $x := 2$;	else $x_1 := 2$;
	$x_2 := \phi(x_0, x_1)$;
... x x_2 ...

A ϕ -function is a function whose value is equal to one of its inputs. Which input depends on which CFG path reached the ϕ -function. The compiler inserts ϕ -functions at places where the program merges two or more values with the same name. The ϕ -

¹ Adding ϕ -functions increases the intermediate representation (IR) size. In theory, this can result in a quadratic increase in the IR size. The compiler community's practical experience to date is that this is not a problem.

function is not an executable statement in the same sense that other assignments are; rather, it gives a unique name to the merged value of x .

SSA form allows the convenient expression of a variety of data-flow analyses. Quick access through use-def chains and the manifestation of merge points simplify a number of problems. In addition, use-def chains and SSA form allow the old bit vector and integer vector analyses to be replaced with *sparse* analyses. A sparse analysis does not carry a vector of every interesting program datum to every instruction. Instead, it carries just the information needed at an instruction to that instruction. For these reasons, this thesis will make extensive use of SSA form.

The main results of this thesis are (1) a framework for expressing and combining analyses, (2) a method for showing when this is profitable, (3) a sparse analysis combining *Conditional Constant Propagation* [49] and *Global Congruence Finding* [2] in $O(n \log n)$ time, and (4) an implementation with experimental results. Additionally, the thesis discusses a global code motion technique that, when used in conjunction with the combined analysis, produces many of the effects of *Partial Redundancy Elimination* [36, 18] and *Global Value Numbering* [37].

1.4 Organization

To make the presentation clearer, we will use integer arithmetic for all our examples. All the results apply to floating-point arithmetic, subject to the usual caveats concerning floating point. Floating-point arithmetic is neither distributive nor associative, and intermediate results computed at compile time may be stored at a different precision than the same results computed at run time.

This thesis has nine chapters. Chapter 2 states the optimistic assumption in a mathematically rigorous way with examples. It then furnishes minimum requirements for any optimistic analysis.

Chapter 3 defines a general data-flow framework. It uses the optimistic assumption to demonstrate when two optimizations can be profitably combined. Constant propagation,

unreachable code elimination, and global congruence finding are combined with a simple $O(n^2)$ algorithm.

Chapter 4 presents a more efficient $O(n \log n)$ algorithm for combining these optimizations. This combined algorithm also folds in various techniques from local value numbering.

For efficient analysis, quads contain use-def chains along with variable names. Chapter 5 shows how to remove the redundant names, leaving only the use-def chains. It also folds the CFG into the use-def chains, making a single level intermediate representation. The resulting representation is compact and efficient.

Chapter 6 shows the results of the complete implementation. It compares program improvement times for the combined algorithm versus the classic, separate pass approach. The chapter also shows the compile times for the different approaches.

Chapter 7 presents a powerful global code motion algorithm. When used in conjunction with the intermediate representation in Chapter 5, the combined algorithm becomes much stronger. Removing some control dependencies allows the combined algorithm to mimic some of the effects of *Partial Redundancy Elimination* and *Global Value Numbering*.

Optimistic analysis must be global, but pessimistic analysis can be local (*i.e.*, peephole). Chapter 8 presents a strong peephole technique, one that gets within 95% of what the best global technique does. This peephole optimization can occur during parsing if SSA form is available. The chapter also presents a method for incrementally building SSA form and experimental results for this technique.

Finally, Chapter 9 presents conclusions and directions for future research.

Chapter 2

The Optimistic Assumption

*If all the arts aspire to the condition of music,
all the sciences aspire to the condition of mathematics.*
— George Santayana (1863-1952)

Before a compiler can improve the code it generates, it must understand that code. Compilers use many techniques for understanding code, but a common one is called *data-flow analysis*. Data-flow analysis tracks the flow of data around a program at compile time. The type of data depends on the desired analysis. Central to most data-flow analyses is the idea of a set of facts. During analysis, this set of facts is propagated around the program. Local program facts are added or removed as appropriate. When the analysis ends, the facts in the set hold true about the program. It is fitting that we begin our journey into program analysis with a look at sets.

I will start by discussing what it takes to discover a set. Then I will talk about data-flow frameworks in terms of discovering a set. The set view of data-flow analysis gives us a better intuition of what it means to combine analyses. In this chapter we will briefly look at a constant propagation framework. In the next chapter we will specify data-flow frameworks for constant propagation, unreachable code elimination and global value numbering, and find that they can be easily combined. For each analysis (and the combination) we will look at some small example programs.

Central to most data-flow frameworks is the concept of a lattice. Points of interest in the program are associated with lattice elements. Analysis initializes program points to some ideal lattice element, usually called “top” and represented as T . At this point, some of the lattice values may conflict with the program. Analysis continues by strictly lowering the lattice elements until all conflicts are removed. This stable configuration is called a fixed point. If the analysis stops before reaching a fixed point, the current program point

values are potentially incorrect. In essence, T represents an optimistic choice that must be proven to be correct.

An alternative approach is to start all program points at the most pessimistic lattice element, \perp (pronounced “bottom”). At this point there are no conflicts, because \perp means that the compiler knows nothing about the run-time behavior of the program. Analysis continues by raising lattice elements, based on the program and previously raised lattice elements. If analysis stops before reaching a fixed point, the current program point values are correct, but conservative — the analysis fails to discover some facts which hold true.

In many data-flow frameworks, there exist programs for which the pessimal approach will *never* do as well as the optimistic approach. Such programs appear several times in the test suite used by the author. This chapter explores the “optimistic assumption” and why it is critical to the ability of an optimistic analysis to best a pessimistic analysis.

2.1 The Optimistic Assumption Defined

Enderton [19] defines a *set* as a collection of *rules* applied to some *universe*. Think of the rules as assertions that all hold true when applied to the desired set. While these rules can define a set, they do not tell how to construct the set.

We will restrict our rules to being monotonic with *subset* as the partial order relation. Now we can view our restricted rules as functions, mappings from universe to universe. Since **all** rules must hold true on the desired set, we will form a single mapping function that applies all rules simultaneously and unions the resulting sets.²

We can apply this mapping function until we reach a fixed point, a set of elements that, when the mapping function is applied to the set, yields the same set back. There are two ways to apply the mapping function to build a set:

1. **Bottom-up:** Start with the empty set. Apply the mapping function. Initially only the base-cases, or zero-input rules, produce new elements out. Continue applying the mapping function to the expanding set, until closure. Because our rules are

² We could choose intersection instead of union, but this makes the appearance of the rules less intuitive.

monotonic, elements are never removed. This method finds the *Least Fixed Point (lfp)*.

2. **Top-down:** Start with the complete set, the set with every element in the universe. Apply all rules. Some elements will not be produced by any rule, and will not be in the final conjunction. Continue applying the mapping function, removing elements not produced by any rule, until closure. This finds the *Greatest Fixed Point (gfp)*.

In general, the top-down approach can yield a larger set. It never yields a smaller set. We leave until Chapter 3 the proof that the top-down method finds the *gfp*.

Definition 1: We use the *optimistic assumption* when we find a set using the top-down approach instead of the bottom-up approach.

The following two examples will make these ideas more concrete. The first example defines sets that are equal for both approaches. The second example gives rules that define two different sets, depending on the approach.

Example 1: Let the universe be the set of natural numbers \mathbf{N} , $\{1,2,3,\dots\}$. We describe a set using these two rules: “ f : 1 is in the set” and “ g : if x is in the set, then $x+2$ is in the set”, as shown in Figure 2.1. The boxed numbers exist in both sets (and are generated by either approach); crossed-out numbers exist in neither set (and are not generated by either approach). When we build the set using the bottom-up approach we apply f to place 1 in the set. Then, we apply g to 1 and place 3 in the set, etc. Eventually we build up the set of positive odd numbers. The top-down yields the same set. We start with all positive integers, including 4, in the set. For 4 to remain in the set we require $g^{-1}(4) = 2$, to be in the set. However, $g^{-1}(2) = 0$ and 0 is not in our universe (or our set), so we must remove 2, then 4, and all even numbers, from the set. Again we build the set of positive

Figure 2.1 Defining a set using $f() = 1$ and $g(x) = x + 2$

odd numbers.

Alternatively we can think of these rules as being a map from \mathbf{N} to \mathbf{N} . For the top-down case, we start with an initial set, S_0 , of all the natural numbers. We then use the rules to map $S_0 \mapsto S_1$. However, S_1 does not have 2 in the set because neither f nor g produces 2 when applied to any natural number. If we repeat the mapping, $S_1 \mapsto S_2$, then S_2 contains neither 2 nor 4 (4 is missing because 2 is missing in S_1). When we repeat to a fixed point, we find the set of positive odd integers.

Example 2: We use the same universe, but we use the rules : “ f : 1 is in the set” and “ g : if x is in the set, then x is in the set”. In Figure 2.2, we see that the top-down and bottom-up approaches yield different sets. As in Example 1, boxed numbers exist in both sets. Plain numbers exist only in the top-down set. Building the set by the bottom-up method starts by using f to place 1 in the set. When we apply g to all elements of the set (*i.e.*, 1), we get only the element 1 and the set is trivially closed under f and g . However, with the top-down approach, we initially fill the set from the universe. We can apply g to any element and thus find a rule for that element. The top-down approach yields a set equal to the entire universe of natural numbers.

Again, we can view the rules as a map from \mathbf{N} to \mathbf{N} . For the top-down case we start with an initial set, S_0 , of all natural numbers. We then use the rules to map $S_0 \mapsto S_1$. Now, however, S_1 is identical to S_0 . Rule g maps everything in S_0 into S_1 . We find the fixed point immediately, and it is the set \mathbf{N} . Unlike in example 1, the top-down and bottom-up approaches give different sets in example 2.

The crucial difference between example 1 and example 2 is the cycle in rule g , which defines an infinitely long path. If the rules and elements do not form infinitely long back-

Figure 2.2 Defining a set using $f() = 1$ and $g(x) = x$

wards paths, then the two approaches always give the same final set. The bottom-up approach can never form an infinitely long backwards path. The bottom-up approach cannot “prime the pump”; it cannot produce the elements needed to complete a cycle. The top-down approach starts with the elements in any cycle all existing; their existence allows the application of the rules in the cycle which in turn define the cycle’s elements. The key idea of this section is:

Sets are different when rules and elements form infinitely long paths of dependencies.

As we will see in later sections, the rules and elements from our data-flow frameworks will form cycles of dependencies at program loops. Thus a top-down analysis can yield more facts than a bottom-up analysis when working with loops. This also implies that for loop-free programs, pessimistic and optimistic analyses perform equally well.

2.2 Using the Optimistic Assumption

In the chapters that follow we will express various common forms of analysis as finding sets of elements. We achieve the best answer (*i.e.*, the sharpest analysis) when these sets are as large as possible.³ In general there is not a unique largest set, a *gfp*, for any given collection of rules. For our specific problems there will always be a *gfp*.⁴

We want to express the data-flow analysis *constant propagation* as the discovery of a set of facts. To make this discussion clearer, we place the program in SSA form, so the program assigns each variable once. We also convert any high-level language expressions into collections of quads.

Definition 2: We define *constant propagation* as a method for finding a set of variables that are constant on all executions for a given program in SSA form.

³ For some data-flow analyses, we will invert the usual sense of the set elements. For LIVE, elements of the universe will be assertions that a particular variable is dead at a particular point in the program. The largest solution set means that the most variables are dead over the most program points.

⁴ Actually, with MEET defined as the subset relation and with a class of functions $\mathcal{F}: S \mapsto S$ (where S is a set from above) where each $f \in \mathcal{F}$ applies some rules to S and returns S augmented with the elements so defined, then each f is trivially monotonic and we have a *gfp* [46]. However, it is difficult to define constant propagation using the subset relation for MEET, so we will have to prove monotonicity on a function-by-function basis.

Our universe is all the pairs $\langle \text{variable}, \text{integer} \rangle$ for each variable in the program and all integers. We derive our rules directly from the program. For the quad “ $q := a + b;$ ” we get the rule:

$$h(\hat{x}, \hat{y}) \equiv \begin{cases} \langle q, c_1 + c_2 \rangle & \text{if } \hat{x} = \langle a, c_1 \rangle \text{ and } \hat{y} = \langle b, c_2 \rangle \\ \langle \cdot \rangle & \text{otherwise} \end{cases}$$

This rule says that if the variable a is paired with some integer c_1 and b is paired with c_2 , then q can be paired with $c_1 + c_2$. To put it another way, if a is 2 and b is 3, then $a + b$ is 5. In the constant propagation lattice we treat:

\top as all the pairs $\forall i, \langle x, i \rangle$,

c_0 as the pair $\langle x, c_0 \rangle$, and

\perp as the empty set of pairs.

A variable y computes the constant 5 if the pair $\langle y, 5 \rangle$ is in the final set. If all pairs $\dots, \langle y, -1 \rangle, \langle y, 0 \rangle, \langle y, 1 \rangle, \dots$ are in the final set, then y simultaneously computes all constants; y 's value is undefined.

The bottom-up approach starts with quads of the form “ $x := 1;$ ” (similar to the earlier f rule, but specifically for variable x : “The pair $\langle x, 1 \rangle$ is in the set”). That approach then applies rules (e.g., $h(\hat{x}, \hat{y})$) to existing pairs until closure is reached. The top-down approach starts with **all** $\langle x, i \rangle$ pairs and throws away pairs not produced by any rule. Without code loops, the rules cannot form cycles of dependencies, and the two approaches get the same answer.

Since we are using SSA form, we have ϕ -functions. ϕ -functions are treated like $+$ and \times (i.e., like any other simple program expression). For the quad “ $q := \phi(a, b);$ ” we get the rule:

$$h(\hat{x}, \hat{y}) \equiv \begin{cases} \langle q, c_0 \rangle & \text{if } \hat{x} = \langle a, c_0 \rangle \text{ and } \hat{y} = \langle b, c_0 \rangle \\ \langle \cdot \rangle & \text{otherwise} \end{cases}$$

If the same quad resides in a loop, it has the form “ $b := \phi(a, b);$ ”. The bottom-up approach finds nothing. There are no elements $\langle b, c_0 \rangle$; there is nothing to prime the cycle of dependencies. However, the top-down approach finds a $\langle b, c_0 \rangle$ pair for every matching

$\langle a, c_0 \rangle$ pair. To put it another way, if a constant is assigned to a before the loop and we only merge a with the copy of itself from the loop, then a will be a constant in the loop.

2.3 Some Observations about the Optimistic Assumption

A bottom-up analysis can be stopped prematurely; a top-down analysis cannot. Both the bottom-up and top-down approaches will iterate until reaching a fixed-point. However, the bottom-up approach can be stopped prematurely. Every element in the set exists because of some rule; optimizations based on the information in the set will be correct (but conservative). Stopping the top-down approach before reaching the *gfp* means that there are elements in the set that do not have a corresponding rule. Optimizations using these elements can be incorrect.

Top-down analysis requires checking an arbitrarily large number of rules and elements. In bottom-up analysis, adding a new element requires only the application of some rule to some set of elements. If we constrain the rules to have a constant number of inputs and to run in constant time, then adding any element requires only a constant amount of time. However, for top-down analysis, checking to see if some element should remain in the set may require checking all the rules and elements in some arbitrarily large cycle of dependencies. For each of the analyses we will examine, it is possible to apply the bottom-up approach using strictly local⁵ techniques. We limit our top-down analyses to global, batch-oriented techniques.

Bottom-up methods can transform as they analyze. Because the solution set for bottom-up analyses is always correct, transformations based on intermediate solutions are valid. Every time analysis adds new elements to the solution set, transformations based on the new elements can be performed immediately. For some analyses, we can directly represent the solution set with the intermediate representation. To add new elements to the solution, we transform the program. We will present online versions of pessimistic analy-

⁵ Local is used in the mathematical (as opposed to the data-flow) sense. To determine if we can add any given element, we will inspect a constant number of other elements that are a constant distance (1 pointer dereference) away.

ses in Chapter 7, in which we solve a pessimistic analysis by repeatedly transforming the program.

Many published data-flow analyses use the optimistic assumption separately, but do not use the optimistic assumption between analyses.⁶ A combination of optimizations, taken as a single transformation, includes some optimistic analyses (each separate phase) and some pessimistic analyses (information between phases).

⁶ Classic analysis have historically been pessimistic, presumably because proof of correctness is easier. In a bottom-up analysis there is never a time when the information is incorrect.

Chapter 3

Combining Analyses, Combining Optimizations

*O that there might in England be
A duty on Hypocrisy,
A tax on humbug, an excise
On solemn plausibilities.
— Henry Luttrell (1765-1881)*

3.1 Introduction

Modern optimizing compilers make several passes over a program's intermediate representation in order to generate good code. Many of these optimizations exhibit a phase-ordering problem. The compiler discovers different facts (and generates different code) depending on the order in which it executes the optimizations. Getting the best code requires iterating several optimizations until reaching a fixed point. This thesis shows that by combining optimization passes, the compiler can discover more facts about the program, providing more opportunities for optimization.

Wegman and Zadeck showed this in an *ad hoc* way in previous work — they presented an algorithm that combines two optimizations. [49] This thesis provides a more formal basis for describing combinations and shows when and why these combinations yield better results. We present a proof that a simple iterative technique can solve these combined optimizations. Finally, we combine *Conditional Constant Propagation* [49] and *Value Numbering* [2, 12, 13, 37] to get an optimization that is greater than the sum of its parts.

3.2 Overview

Before we describe our algorithms, we need to describe our programs. We represent a program by a *Control Flow Graph* (CFG), where the edges denote flow of control and the vertices are basic blocks. Basic blocks contain a set of assignment statements represented as quads. Basic blocks end with a special final quad that may be a **return**, an **if** or empty (fall through). We write program variables in lower case letters (*e.g.*, x , y). All variables are initialized to T, which is discussed in the next section. To simplify the presentation, we restrict the program to integer arithmetic. The set of all integers is represented by \mathbb{Z} .

Assignment statements (quads) have a single function on the right-hand side and a variable on the left. The function op is of a small constant arity (*i.e.*, $x := a \text{ op } b$). Op may be a constant or the identity function, and is limited to being a k -ary function. This is a reasonable assumption for our application. We run the algorithm over a low-level compiler intermediate representation, with $k \leq 3$. We call the set of op functions OP .

We assume the program was converted into *Static Single Assignment* (SSA) form [15]. The original program assigns values to names at multiple definition points. In the SSA form, each name corresponds to a single definition point. By convention, we generate the new names of SSA form by adding subscripts to the original names. This makes the relationship textually obvious to a human reader. Wherever two definitions of the same original variable reach a merge point in the program's control flow, a ϕ -function is inserted in the SSA form. The ϕ -function defines a unique name for the merged value. This is written $x_1 := \phi(x_0, x_2)$. The ϕ -function assignments are treated like other quads; only the quad's function distinguishes the ϕ . We give some sample code in SSA form in Figure 3.1.

Normal	SSA
int $x := 1$;	int $x_0 := 1$;
do {	do { $x_1 := \phi(x_0, x_3)$;
if ($x \neq 1$)	if ($x_1 \neq 1$)
$x := 2$;	$x_2 := 2$;
	$x_3 := \phi(x_1, x_2)$;
} while ($pred()$);	} while ($pred()$);
return x ;	return x_3 ;

Figure 3.1 Sample code in SSA form

After the renaming step, the program assigns every variable exactly once.⁷ Since expressions only occur on the right-hand side of assignments, every expression is associated with a variable. There is a one-to-one correlation between variables and expressions; the variable name can be used as a direct map to the expression that defines it. In our implementation, we require this mapping to be fast.⁸ Finally, we define N to be the number of statements in the SSA form. In SSA form the number of ϕ -functions inserted can be quadratic in the size of the original code; the community's practical experience to date has shown that it is usually sublinear in the size of the original code.

3.2.1 Monotone Analysis Frameworks

To combine several optimizations, we first describe them in a common *monotone analysis framework* [14, 30, 45]. Briefly, a monotone analysis framework is:

1. A lattice of inferences we make about the program. These are described as a complete lattice $\mathcal{L} = \{A, \top, \perp, \cap\}$ with height d , where:
 - a) A is a set of inferences.
 - b) \top and \perp are distinguished elements of A , usually called “top” and “bottom” respectively.
 - c) \cap is the *meet* operator such that for any $a, b \in A$,

$$\begin{aligned} a \cap a &= a, & (\text{idempotent}) \\ a \cap b &= b \cap a, & (\text{commutative}) \\ a \cap (b \cap c) &= (a \cap b) \cap c, & (\text{associative}) \\ a \cap \top &= a, \\ a \cap \perp &= \perp, \end{aligned}$$
 - d) d is the length of the longest chain in \mathcal{L} .
2. A set of monotone functions F with arity $\leq k$ used to approximate the program, defined as $F \subseteq \{f : \mathcal{L} \rightarrow \mathcal{L}\}$ containing the identity function id and closed under composition and pointwise meet.

⁷ This is the property for which the term *static single assignment* is coined.

⁸ In fact, our implementation replaces the variable name with a pointer to the expression that defines the variable. Performing the mapping requires a single pointer lookup.

3. A map $\gamma : OP \rightarrow F$ from program primitives to approximation functions. In general, all the approximation functions are simple tables, mapping lattice elements to lattice elements.⁹ We do not directly map the CFG in the framework because some frameworks do not maintain a correspondence with the CFG. This means our solutions are not directly comparable to a *meet over all paths* (MOP) solution like that described by Kam and Ullman [30]. Our value-numbering solution is such a framework.

We say that $a \succeq b$ if and only if $a \cap b = b$, and $a \succ b$ if and only if $a \succeq b$ and $a \neq b$. Because the lattice is complete, \cap is closed on A .

The lattice height d is the largest n such that a sequence of elements x_1, x_2, \dots, x_n in \mathcal{L} form a chain: $x_i \succ x_{i+1}$ for $1 \leq i < n$. We require that \mathcal{L} have the finite descending chain property – that is, d must be bounded by a constant. For the problems we will examine, d will be quite small (usually 2 or 3).

We assume that we can compute $f \in F$ in time $O(k)$, where k is the largest number of inputs to any function in F . Since $k \leq 3$ in our implementation, we can compute f in constant time.

3.2.2 Monotone Analysis Problems

When we apply a monotone analysis framework to a specific program we get a *monotone analysis problem* – a set of simultaneous equations derived directly from the program. Variables in the equations correspond to points of interest in the program; each expression in the program has its own variable. Associated with each variable is a single inference. Program analysis substitutes approximation functions (chosen from F using γ) for the actual program primitive functions and solves the equations over the approximation functions. (In effect, analysis “runs” an approximate version of the program.) By design, the equations have a maximal solution called the *Greatest Fixed Point (gfp)* [14, 46].¹⁰

⁹ Some of our mappings take into account information from the CFG. Here we are taking some notational liberty by defining the mapping from only OP to F . We correct this in our implementation by using an operator-level (instead of basic block level) *Program Dependence Graph* (PDG) in SSA form [21, 38]. Such a representation does not have a CFG or any basic blocks. Control information is encoded as inputs to functions like any other program variable.

¹⁰ The properties described in Section 3.2.1 ensure the existence of a *gfp* [46]. These systems of equations can be solved using many techniques. These techniques vary widely in efficiency. The more expensive techniques can

Functions in F represent complete programs via composition. Monotonicity gives us some special properties: the composition of monotonic functions is also monotonic. Also the composition is a function onto \mathcal{L} :

$$\forall f, g \in F, f : \mathcal{L} \rightarrow \mathcal{L}, g : \mathcal{L} \rightarrow \mathcal{L} \Rightarrow f \circ g : \mathcal{L} \rightarrow \mathcal{L}$$

To solve the set of equations, we set each variable to T and then repeatedly compute and propagate local solutions. In effect, the variables “run downhill” to the solution. The limit to k -ary approximation functions ensures that we can compute quickly and infrequently. The bound on chain length limits the number of forward, or downhill, steps to a finite number. Monotonicity ensures that running downhill locally cannot improve the global solution. This means that the first solution we find is also the best solution. We will prove this formally in Section 3.4.

3.2.3 Combining Frameworks

Given any two frameworks, \mathcal{A} and \mathcal{B} , a framework that combines them yields better information if and only if their solutions interact. The solution to \mathcal{A} must rely on the solution to \mathcal{B} ; similarly \mathcal{B} must rely on the solution to \mathcal{A} . If they are not interdependent, a careful ordering produces the same answers as the combined framework.

To combine two frameworks, we combine the sets of equations from each framework. The equations of \mathcal{A} implicitly reference facts derived by the equations of \mathcal{B} , and *vice-versa*. We make explicit the implicit references to the equations from the other set. We must prove that the combined equations are still monotonic and therefore represent a monotone analysis framework. The combined framework still has a maximal solution; it may not be equal to the combined maximal solution of the individual problems. If, in fact, it is identical to the combination of the individual solutions, we have gained nothing by combining the frameworks (*i.e.*, it was not profitable).

To demonstrate these ideas more clearly, we will work an extended example — combining simple constant propagation and unreachable code elimination. These optimizations are well known and widely used. Wegman and Zadeck have shown an algorithm that

solve some systems of equations that the less efficient cannot. In general, the difference in efficiency has led classical compilers to use the least expensive method that will solve a given problem.

combines them, *Conditional Constant Propagation* (CCP) [49]. It is instructive to compare their algorithm with our framework-based approach. As a final exercise, we combine CCP with partition-based *Global Value Numbering* (GVN) [2, 37] to obtain a new optimization strictly more powerful than the separate optimizations. The combination runs in $O(N^2)$ time. In Chapter 4, we derive a more complex algorithm which solves the problem in time $O(N \log N)$.

In our technique, the equations are derived directly from the intermediate representation. For the purposes of this chapter, the intermediate representation is the equations. We use a technique from *abstract interpretation*, and associate an approximation function γ chosen from F with every primitive function in the program. Because we restrict the form of the equations (see Section 3.2.1), we can find the maximal solution using an iterative technique in time $O(nk^2d)$ where n is the number of equations to solve (often equal to N , the number of statements in the program), k is largest number of inputs to any one function, and d is the height of the lattice.

3.3 Simple Constant Propagation

Simple constant propagation looks for program expressions that compute the same value on all executions of the program. It can be cast in a monotone analysis framework. It conservatively approximates the program's control flow by assuming that all basic blocks and all quads are executable. Thus, control flow has no explicit expression in the data-flow equations. Each assignment defines an expression and a variable. The inference the variable holds tells us whether the expression computes a constant.

For our inferences we use the standard constant propagation lattice \mathcal{L}_c with the elements $\mathbb{Z} \cup \{\top, \perp\}$ as shown in Figure 3.3. Figure 3.3 also shows the meet operator, \cap . The notation “ $(c_0 = c_1) ? c_0 : \perp$ ” means “if c_0 is equal to c_1 then c_0 else \perp ”. For every primitive function in the program we need a corresponding monotonic function $f \in F$. For ϕ -functions, we use the meet operator. We extend the other primitives to handle \top and \perp . As an example look at $+: \mathbb{Z} \times \mathbb{Z} \rightarrow \mathbb{Z}$. The corresponding function is $f_+ : \mathcal{L}_c \times \mathcal{L}_c \rightarrow \mathcal{L}_c$. Figure 3.2 defines f_+ by replacing op with $+$. The application $f_{op}(\top, \perp)$ is \top instead of \perp , meaning that applying a function to undefined inputs yields undefined results (as opposed

Figure 3.3 The constant propagation lattice \mathcal{L}_c and meet operator

to unknown results).¹¹ This embodies the idea that we do not propagate information until all the facts are known.

For functions with zero elements we use a more precise (and more complex) extension. Multiply is extended in Figure 3.4 so that $f_\star(0, \perp)$ is 0 rather than \perp . This reflects the fact that zero times anything is zero. As shown in the figure, the function results are monotonically decreasing¹² both left to right and top to bottom. Thus f_\star is a monotonic func-

$$f_{op} : \mathcal{L}_c \times \mathcal{L}_c \rightarrow \mathcal{L}_c$$

f_{op}	T	c_0	\perp
T	T	T	T
c_1	T	$c_0 \text{ op } c_1$	\perp
\perp	T	\perp	\perp

Figure 3.2 Extending functions to \mathcal{L}_c

¹¹ *Unknown* values are values that cannot be discovered at compile time. There are many unknown values in a typical program. The compiler must emit code to compute these values at run time. For *undefined* values, the compiler can choose any value it wants.

$$f_* : \mathcal{L}_c \times \mathcal{L}_c \rightarrow \mathcal{L}_c$$

f_*	T	0	c_0	\perp
T	T	T	T	T
0	T	0	0	0
c_1	T	0	$c_0 \times c_1$	\perp
\perp	T	0	\perp	\perp

Figure 3.4 Extending multiply to \mathcal{L}_c

tion, but maintains information in more cases than the corresponding function without the special case for zero.

In Figure 3.5 we generate the equations for a small program in SSA form. For every variable x in the program, we have an equation defining V_x . For the assignment “ $x_0 := 1$,” we generate the equation $V_{x_0} = 1$. In this case, “1” is a constant function from F . Because V_{x_0} is cumbersome, we will write x_0 instead. The different uses of x_0 will be obvious from context.

For the ϕ -functions we use the meet operator. The function $\neq : \mathbf{Z} \times \mathbf{Z} \rightarrow \mathbf{Z}$ returns 0 if the inputs are equal, and 1 if the inputs are not equal. We extend \neq to f_* as shown in Figure 3.2. Assume that the loop controlling predicate $pred()$ is beyond the ability of the compiler to analyze, possibly a keyboard read. Solving the equations by inspection shows that $x_0 = 1$, $x_1 = 1 \cap x_3$ and so x_1 cannot be higher than 1, $x_3 = 1 \cap 2 = \perp$, and thus $x_1 = x_3 = b = \perp$. In short, no new constants are found.

SSA Program	Equations
int $x_0 := 1$;	$x_0 = 1$
do { $x_1 := \phi(x_0, x_3)$;	$x_1 = x_0 \cap x_3$
$b := (x_1 \neq 1)$;	$b = f_*(x_1, 1)$
if (b)	
$x_2 := 2$;	$x_2 = 2$
$x_3 := \phi(x_1, x_2)$;	$x_3 = x_1 \cap x_2$
while ($pred()$);	$x_{pred} = \perp$
return x_3 ;	

Figure 3.5 Simple constant propagation example

¹² Two integers are incomparable in the lattice, thus 0 is neither greater than nor less than $c_0 \times c_1$.

3.4 Finding the Greatest Fixed Point

In this section we show that the iterative technique works on monotone analysis frameworks. That is, we show that initializing a system of monotonic equations to \top and successively solving the equations eventually yields the *gfp*. We start with Tarski [46], who proved that every monotone function $f: \mathcal{L} \rightarrow \mathcal{L}$ has a *gfp* in a complete lattice \mathcal{L} .

Since f is monotone, successive applications of f to \top descend monotonically:

$$\top \succeq f(\top) \succeq f^2(\top) \succeq \dots$$

Since the lattice is of bounded depth, a fixed point $u = f^d(\top) = f^{d+1}(\top)$ is eventually reached. We cannot have $u \succ \text{gfp}$ because *gfp* is the **greatest** fixed point (and u is a fixed point). Suppose we have the reverse situation, $\text{gfp} \succ u$. Then the applications of f must form a descending chain that falls past the *gfp*. There must be some i such that $\dots f^i(\top) \succ \text{gfp} \succ f^{i+1}(\top) \dots$. By the monotonicity of f we have $f^i(\top) \succ \text{gfp} \Rightarrow f^{i+1}(\top) \succeq f(\text{gfp})$. Since $f(\text{gfp}) = \text{gfp}$ we have $f^{i+1}(\top) \succeq \text{gfp}$, a contradiction. Therefore $u = \text{gfp}$, and successive applications of f to \top yield the *gfp*.

We now need to represent a system of monotonic equations as a simple monotonic function f . We extend the lattice \mathcal{L} to tuples in lattice $\vec{\mathcal{L}}$. We define $\vec{\mathcal{L}}$ to be a lattice whose elements are n -tuples of \mathcal{L} elements. We use the notation $\{x_0, x_1, \dots, x_n\} = \vec{x} \in \vec{\mathcal{L}}$ to refer to a tuple of \mathcal{L} elements. We define $\vec{\mathcal{L}}$'s meet operator as element-wise meet over \mathcal{L} elements:

$$\vec{x} \vec{\cap} \vec{y} = \{ x_0 \cap y_0, x_1 \cap y_1, \dots, x_n \cap y_n \}$$

$\vec{\mathcal{L}}$ is a complete lattice with the finite descending chain property. We define $\vec{f}: \vec{\mathcal{L}} \rightarrow \vec{\mathcal{L}}$ as a monotonic function that is a collection of monotonic functions $f_i: \vec{\mathcal{L}} \rightarrow \mathcal{L}$ from the tuple lattice to the regular lattice:

$$\vec{f}(\vec{x}) = \{ f_0(\vec{x}), f_1(\vec{x}), \dots, f_n(\vec{x}) \}$$

Therefore $\vec{y} = \vec{f}(\vec{x})$ defines a system of monotonic equations:

$$\begin{array}{rcl} y_0 & = & f_0(\vec{x}) \\ y_1 & = & f_1(\vec{x}) \\ \vdots & & \vdots \\ y_n & = & f_n(\vec{x}) \end{array}$$

Each of the functions f_0, f_1, \dots, f_n takes an n -length tuple of \mathcal{L} elements. In the problems that we are solving, we require that only k ($0 \leq k \leq n$) elements from \mathcal{L} are actually used. That is, f_i takes as input a k -sized subset of \vec{x} . Unfortunately the solution technique of repeatedly applying \vec{f} until a fixed point is reached is very inefficient. $\vec{\mathcal{L}}$ has a lattice height of $O(nd)$, and each computation of \vec{f} might take $O(nk)$ work for a running time of $O(n^2kd)$. The next section presents a more efficient technique based on evaluating the single variable formulation (f_i rather than \vec{f}).

3.5 Efficient Solutions

To provide efficient solutions, we solve these equations $\vec{y} = \vec{f}(\vec{x})$ with a simple iterative worklist technique [27]. The sparseness of the equations makes the algorithm efficient.

1. Initialize all equation variables x_i to \top .
2. Place all equations on a worklist w .
3. While w is not empty do:
 - a) Remove an equation " $y_i = f_i(\vec{x})$ " from worklist w .
 - b) Solve for y_i using the values of other x_i variables.
 - c) If $y_i \neq x_i$, then set x_i to y_i and place all equations that use x_i back on w .

The f_i functions are all monotonic. As the inputs to the functions drop in the lattice, the defined variable can only go lower in the lattice. Because the lattice has height d , a variable can drop (and change) at most d times. Each function (expression in the program) is on the worklist once per time an input drops in the lattice, or $O(kd)$ times. Each time a function is removed from the worklist it takes time $O(k)$ to evaluate. Total evaluation time per function is $O(k^2d)$, and the total running time is $O(nk^2d)$.

For simple constant propagation, the number of equations n is the number of statements N in the SSA form of the program. If k , the arity of the functions, is small and d is 2, the time bound simplifies to $O(N)$.

3.6 Unreachable Code Elimination

We do the same analysis for unreachable code elimination that we did for simple constant propagation. We seek to determine if any code in the program is not executable, either because a control-flow test is based on a constant value or because no other code jumps to it. Our inferences are to determine if a section of code is reachable, expressed as a two-element lattice \mathcal{L}_u with elements $\{\mathcal{U}, \mathcal{R}\}$. \mathcal{U} is unreachable; \mathcal{R} is reachable. We define the functions $+$ and \cdot like Boolean **Or** and **And** in Figure 3.6. During this analysis the only constant facts available are literal constants. So we define \neq to return \mathcal{U} if both inputs are textually equal and \mathcal{R} otherwise.

$\cdot : \mathcal{L}_u \times \mathcal{L}_u \rightarrow \mathcal{L}_u$			$+: \mathcal{L}_u \times \mathcal{L}_u \rightarrow \mathcal{L}_u$		
\cdot	\mathcal{U}	\mathcal{R}	$+$	\mathcal{U}	\mathcal{R}
\mathcal{U}	\mathcal{U}	\mathcal{U}	\mathcal{U}	\mathcal{U}	\mathcal{R}
\mathcal{R}	\mathcal{U}	\mathcal{R}	\mathcal{R}	\mathcal{R}	\mathcal{R}

Figure 3.6 Or, And defined over \mathcal{L}_u

In Figure 3.7 we generate the equations for the same example as before. For readability we define **F** as a synonym for 0 and **T** as any integer other than 0. The starting statement S_0 is clearly reachable. Statement S_1 is reachable if we can fall into it from S_0 or we can reach the bottom of the loop (statement S_6) and the loop predicate is not always false. We generate the remaining equations in a similar fashion. Our equations are compositions of monotonic functions, and are monotonic.

SSA Program	Equations
int $x_0 := 1$;	$S_0 = \mathcal{R}$
do { $x_1 := \phi(x_0, x_3)$;	$S_1 = S_0 + S_6 \cdot (pred \neq \mathbf{F})$
$b := (x_1 \neq 1)$;	$S_2 = S_1$
if (b)	$S_3 = S_2$
$x_2 := 2$;	$S_4 = S_3 \cdot (b \neq \mathbf{F})$
$x_3 := \phi(x_1, x_2)$;	$S_5 = S_4 + S_3 \cdot (b \neq \mathbf{T})$
while ($pred()$);	$S_6 = S_5$
return x_3 ;	$S_7 = S_6 \cdot (pred \neq \mathbf{T})$

Figure 3.7 Unreachable code elimination example

Because b and $pred$ are not literal constants, all the \neq tests must return \mathcal{R} . The solution is straightforward: everything is reachable.

If we look closely at this example we can see that when we run the program, x_0 gets set to 1, the *if*'s predicate b is always false, and the consequent of the *if* test (S_4) never executes. Neither simple constant propagation nor unreachable code elimination discovers these facts because each analysis needs a fact that can only be discovered by the other.

3.7 Combining Analyses

To improve the results of optimization we would like to combine these two analyses. To do this, we need a framework that allows us to describe the combined system, to reason about its properties, and to answer some critical questions. In particular we would like to know: is the combined transformation correct – that is, does it retain the meaning-preserving properties of the original separate transformations? Is this combination profitable – that is, can it discover facts and improve code in ways that the separate techniques cannot?

If the combined framework is monotonic, then we know a *gfp* exists, and we can find it efficiently. We combine analyses by unioning the set of equations and making explicit the implicit references between the equations. Unioning equations makes a bigger set of unrelated equations. However, the equations remain monotonic so this is safe.

However, if the analyses do not interact there is no profit in combining them. We make the analyses interact by replacing implicit references with functions that take inputs from one of the original frameworks and produce outputs in the other. The reachable equations for S_3 and S_4 use the variable b , which we defined in the constant propagation equations. Instead of testing b against a literal constant we test against an \mathcal{L}_c element. We replace the \neq function with $\leq : \mathcal{L}_c \times \mathbb{Z} \rightarrow \mathcal{L}_u$ defined in Figure 3.8. The \leq function is an example of a function that mixes inputs and outputs between the frameworks. \leq takes an input from the \mathcal{L}_c framework (variable b) and returns a result in the \mathcal{L}_u framework (reachability of the conditional statements).

The meaning of \leq is easily determined. If we know the test is not a constant (i.e., \perp) then both exit paths are reachable. Otherwise the test is a constant and only one exit path is reachable. At first glance this function looks non-monotonic, but **F** and **T** are not comparable in \mathcal{L}_c .

The important question to answer is:

Are the functions that represent interactions between frameworks monotonic?

If they are, then the combined framework is monotonic and we can use all the tools developed to handle monotonic frameworks. If the original frameworks are monotonic and these transfer functions are monotonic, then the combined framework is monotonic. In combining two frameworks the implementor *must prove* this property. Fortunately, reasoning about the monotonicity of these transfer functions is no harder than reasoning about the original frameworks. We represent the transfer functions in our examples with small tables. We determine the functions are monotonic by inspection.

$[\Rightarrow] : \mathcal{L}_u \times \mathcal{L}_c \rightarrow \mathcal{L}_c$			$\leq : \mathcal{L}_c \times \mathcal{Z} \rightarrow \mathcal{L}_u$				
$[\Rightarrow]$	\mathcal{U}	\mathcal{R}	\leq	T	F	T	\perp
T	T	T	F	\mathcal{U}	\mathcal{R}	\mathcal{U}	\mathcal{R}
c	T	c	T	\mathcal{U}	\mathcal{U}	\mathcal{R}	\mathcal{R}
\perp	T	\perp	Testing a predicate				

Unreached code computes **T**

Figure 3.8 Mixed functions for the combined equations

3.7.1 Profitability of Combined Frameworks

The combined framework is only useful when it is profitable. It is profitable when the *gfp* solution computes a value for a mixed function that is higher in the output lattice than the implicit function that the mixed function replaced. If the mixed function's solution is the same as the implicit function's, the equations using the mixed function have no better results than when they use the implicit function. This means the combined solution fares no better than when the implicit functions were used, which implies the combined solution is no better than the individual solutions.

If we have functions from framework \mathcal{L}_c to framework \mathcal{L}_u but not vice-versa, we have a simple phase-ordering problem. We can solve the \mathcal{L}_c framework before the \mathcal{L}_u framework and achieve results equal to a combined framework. The combined framework is only profitable if we also have functions from \mathcal{L}_u to \mathcal{L}_c and the combined *gfp* improves on these mixed functions' results.

Back to our example: the value computed by unreachable code is undefined (\top), so each of the constant propagation equations gets an explicit reference to the appropriate reachable variable. The reachable variable is used as an input to the monotonic infix function $[\Rightarrow] : \mathcal{L}_u \times \mathcal{L}_c \rightarrow \mathcal{L}_c$, also defined in Figure 3.8.

Instead of one equation per statement we have two equations per statement. Each equation has grown by, at most, a constant amount. So, the total size of all equations has grown by a constant factor, and remains linear in the number of statements.

3.7.2 An Example

We give the complete new equations in Figure 3.9. Solving the equations is straightforward but tedious. We present a solution in Figure 3.10 using the iterative technique given in Section 3.5. In this example the boxed terms represent y_i in step 3b (the variable

Program	Equations
int $x_0 := 1$;	$S_0 = \mathcal{Z}$
	$x_0 = [S_0 \Rightarrow 1]$
do { $x_1 := \phi(x_0, x_3)$;	$S_1 = S_0 + S_6 \cdot (pred \leq \mathbf{T})$
	$x_1 = [S_1 \Rightarrow (x_0 \cap x_3)]$
$b := (x_1 \neq 1)$;	$S_2 = S_1$
	$b = [S_2 \Rightarrow f_*(x_1, 1)]$
if (b)	$S_3 = S_2$
$x_2 := 2$;	$S_4 = S_3 \cdot (b \leq \mathbf{T})$
	$x_2 = [S_4 \Rightarrow 2]$
$x_3 := \phi(x_1, x_2)$;	$S_5 = S_4 + S_3 \cdot (b \leq \mathbf{F})$
	$x_3 = [S_5 \Rightarrow (x_1 \cap x_2)]$
} while ($pred()$);	$S_6 = S_5$
	$pred = \perp$
return x_3 ;	$S_7 = S_6 \cdot (pred \leq \mathbf{F})$

Figure 3.9 Combined example

being computed).

The main points of interests are the interactions between the separate analyses in the equations for x_1 , b , S_3 , x_2 and x_3 .

Time 0: x_3 (along with all other variables) is initialized to T or \mathcal{U} .

Time 4: x_1 meets x_0 and x_3 to get the value 1.

Time 6: b is a constant F.

Time 8: S_4 is left marked unreachable (\mathcal{U}). Since S_4 did not change value, the equation setting x_2 is never placed on the worklist.

Time 10: x_3 meets x_1 and x_2 to get the value 1. Since x_3 changed from T to 1, users of x_3 (including x_1 's equation) go back on the worklist.

Time 14: x_1 's original value remains unchanged.

Time	S_0	x_0	S_1	x_1	S_2	b	S_3	S_4	x_2	S_5	x_3	S_6	$pred$	S_7
0	\mathcal{U}	T	\mathcal{U}	T	\mathcal{U}	T	\mathcal{U}	\mathcal{U}	T	\mathcal{U}	T	\mathcal{U}	T	\mathcal{U}

Figure 3.10 Solving the combined example

The solution stabilizes. The combined analysis marks statement S_3 unreachable and knows x_3 is the constant 1. The individual analyses do not find these facts. Repeated applications of these separate analyses cannot discover any more new facts because each new application starts out with no more facts than the first analysis did. However the combined framework does find these facts.

The conditional constant propagation algorithm of Wegman and Zadeck discovers these facts [49]. The improved solution (more knowledge) derives from the interaction made explicit in the equations. Specifically, the combined framework exposes unreachable code precisely because the reachability equations rely on an assumption made by the constant propagation equations and vice-versa. The assumption is optimistic¹³ in the sense that it is not justified by the facts at hand, but must be proven correct. If the assumption is not correct, the equations must be re-evaluated in light of the new (more pessimistic, but more correct) information. However, if the assumption is correct, something new may be discovered.

Thus the reason CCP is an improvement over simple constant propagation and unreachable code elimination is that there **are** interactions. If, in combining frameworks, no implicit interactions are made explicit, the combined framework can not discover additional facts. In such a case the combined framework consists of two independent sets of equations.

3.8 Global Value Numbering

We can formulate a monotone analysis framework for finding congruent expressions. We define two expressions to be *congruent* [2] when:

- the two expressions are the same expression (reflexivity), or
- they compute equivalent functions on congruent inputs, or
- they compute the same constant, or
- one is an identity function on the other.

¹³ Wegman and Zadeck coined the term *optimistic assumption*.

Identity functions arise from direct copies in the input language, from algebraic identities (addition of zero), or from merging congruent values in ϕ -functions.¹⁴

Congruence is a relation that holds between pairs of expressions, so a program of size N has $O(N^2)$ inferences (and $O(N^2)$ equations to solve). We can derive equations involving constant inferences, reachable inferences, and congruence inferences in a straightforward manner. The equations do interact, so there is a benefit in solving the combined problem.

Our inferences are whether or not two expressions are congruent, expressed as a two-element lattice \mathcal{L}_\equiv with elements $\{\equiv, \neq\}$. We overload the functions $+$ and \cdot to work with \mathcal{L}_\equiv elements in the usual way as shown in Figure 3.6. We write C_{xy} for a variable that determines whether expression x is congruent to expression y , x_{op} for the primitive function at expression x , and x_i for the i th input to x_{op} .

The basic congruence equation between expressions x and y looks like:

$$\begin{array}{ll}
 C_{xy} = & (x = y) + \text{Reflexive} \\
 & (x_{op} = y_{op}) \cdot C_{x_1 y_1} \cdot C_{x_2 y_2} \cdots C_{x_k y_k} + \text{Equal functions on congruent inputs} \\
 & (x_{op} = c_0) \cdot (y_{op} = c_0) + \text{Both are the same constant} \\
 & (x_{op} = +) \cdot (x_{1op} = 0) \cdot C_{x_2 y} + \text{Add of a zero} \\
 & (x_{op} = +) \cdot C_{x_1 y_2} \cdot C_{x_2 y_1} + \text{Add is commutative} \\
 & (x_{op} = \phi) \cdot C_{x_1 x_2} \cdot C_{x_1 y} + \text{Merge of congruent values} \\
 & \dots \text{Other identities, i.e., multiply by 1}
 \end{array}$$

The program defines the function values so the function tests (e.g., $x_{op} = +$) can be pre-computed before we solve the general problem. The equations are still complex, but there are a fixed number of special cases, one special case per kind of algebraic identity. The number of inputs to the equation defining C_{xy} is thus fixed by some constant k . All the functions involved in the equation are monotonic, and the composition of these functions is also monotonic. Thus we can use the algorithm in Section 3.5, and achieve a running time of $O(nk^2d)$. Since $n = N^2$ and k and d are constants, running time is $O(N^2)$.

¹⁴ This is a slightly stronger notion of congruence than Alpern, Wegman and Zadeck use. They do not allow for identity functions, merging congruent values or computed constants.

We make *Global Value Numbering* interact with CCP by modifying the C_{xy} equations to use computed constants instead of textual constants, and noting that undefined values can be congruent to anything. The new congruence equation looks like:

$C_{xy} =$...	As before
	$(V_x = T) + (V_y = T) +$	Either is undefined
	$(V_x = V_y = c_0) +$	Both compute same constant
	$(x_{op} = +) \cdot (V_{x_1} \geq 0) \cdot C_{x_2y} +$	Add of a zero
	...	

These congruence equations clearly use values from the \mathcal{L}_c lattice. We add mixed functions for the reverse direction by defining the subtraction of congruent values to yield 0, and the compare of congruent values to yield **T**.¹⁵

Since we have mixed functions going both to and from $\mathcal{L}_=$ and \mathcal{L}_c elements, we have the opportunity to find more congruences, constants and unreachable code than can be found with separate analyses. Figure 3.11 is an example of such code.

```

main()
{
    int x := 1;           // x is the constant 1
    int z := read();      // z is defined but unknown
    int y := z;           // y is congruent to z here
    while( pred() ) {    // some unknown predicate
        if( y ≠ z )      // if we know y and z are congruent
            x := 2;      // then we do not destroy the constant at x
        x := 2 - x;      // destroy easy congruence between x and 1
        if( x ≠ 1 )      // if we know x is a constant
            y := 2;      // then we do not destroy the y-z congruence
    }
    printf("x is %d\n",x); // x is always 1 here
}

```

Figure 3.11 A subtle congruence, a little dead code

3.8.1 Interpreting the Results

Having solved our combined problem, we need to use the results. If the N^2 C_{xy} congruences form an equivalence relation, we have a fairly obvious strategy: pick one expres-

¹⁵ If, during the course of solving the equations, the subtract is of the constants 5 and 3 yielding 2, and the constants are considered congruent, then we have a conflict. Instead of choosing between 2 or 0 we leave the subtract expression at T. The situation is temporary as 5 and 3 cannot remain congruent. This is a good example of an incorrect intermediate state that can legally occur in an optimistic analysis.

sion from each partition to represent all the expressions in that partition. Build a new program from the selected expressions (dropping unreachable code and using constants where possible). However, partitions might contain expressions that are algebraic identities of another expression in the same partition. These expressions cannot be selected to represent the partition because they have an input in the same partition; after replacing all uses in the partition with uses of the representative, the identity will be a copy of itself.

In the presence of undefined variables, the resulting congruences do not have to form an equivalence relation. This is because we define an expression x with $V_x = T$ as being congruent to all other expressions. Such an expression x starts out being congruent to both the constant 3 and the constant 4. If V_x drops below T , the problem resolves itself as the equations are solved. If V_x remains at T (because x is undefined), the congruences between x and 3 and 4 remain. This can lead to some unusual behavior. In the code in Figure 3.12, both tests against x are the constant T . The analysis shows that *both* print statements are always reached.

```
main()
{
    int x;           // x is undefined
    if( x = 3 ) printf("x is 3\n");
    if( x = 4 ) printf("x is 4\n");
}
```

Figure 3.12 Using undefined variables

Most language standards fail to address this particular aspect of using an undefined variable. We believe our interpretation is correct given the facts at hand. The analysis can avoid the unusual behavior by looking for congruence relations that do not form equivalence relations. The analysis can then break an arbitrary congruence (some C_x variable set to \neq) and continue until reaching another (lower) fixed point. This process can continue until an equivalence relation is formed. In the worst case, all congruences are broken, and the result is clearly a trivial equivalence relation. Intuitively, this process of breaking congruences is forcing the analysis to choose between having x congruent to 3 and x congruent to 4.

3.9 Summary

In this chapter, we have shown how to combine two code improvement techniques. We assume that the original transformations can be encoded as monotone analysis frameworks. In our model, we can combine two frameworks, reason about the monotonicity of the combined framework, and solve the combined framework efficiently. Furthermore, the structure of the combined framework shows when a combination can produce better results than repeated application of the original transformations, and, equally important, when it cannot.

To illustrate these points, we showed how to combine constant propagation with unreachable code elimination to derive an algorithm with properties similar to the conditional constant propagation algorithm presented by Wegman and Zadeck [49]. Because the combined framework includes transfer functions that take constant values into unreachable code framework and *vice-versa*, it can discover more constants and more unreachable code than repeated applications of the original transformations.

Finally, we showed how to combine constant propagation, unreachable code elimination, and global value numbering. It is an open question as to what other frameworks can be combined and are profitable to combine. The asymptotic complexity of the presented analysis is $O(N^2)$. It can discover more facts than separate applications of the three transformations.

In general, combining two frameworks is important when it removes a phase ordering problem. The monotone analysis framework for the combined problem will run in $O(nk^2d)$ time, where n is the number of equations, k is the arity of the functions used in the equations, and d is the height of the inference lattice.

Chapter 4

An $O(n \log n)$ Conditional Constant Propagation and Global Value Numbering Algorithm

Make haste, not waste
— anonymous?

4.1 Introduction

We have implemented an $O(n \log n)$ algorithm that combines the analysis portions of *Conditional Constant Propagation* (CCP) [49], *Global Value Numbering* (GVN) [37], and *Global Congruence Finding* [2]. We follow the analysis with a transformation that replaces every set of congruent expressions with a single expression, removes dead and unreachable code, and uses constants where possible. This transformation is followed by a round of global code motion, to force expressions to dominate their uses. The global code motion algorithm is discussed in Chapter 6.

The set of congruent expressions found by this algorithm overlap but do not cover those found by *Partial Redundancy Elimination* (PRE) [36]. This algorithm finds value-congruent expressions, but PRE finds some textually-congruent expressions that are not value-congruent. In addition, the global code motion algorithm hoists loop-invariant code more aggressively than PRE, occasionally lengthening execution paths. Thus, while the combined algorithm with global code motion has many of the effects of PRE, it is not a direct replacement for PRE.

The complexity of the combined algorithm is $O(n \log n)$ instead of the $O(n^2)$ algorithm presented in Chapter 3. We have implemented it, and observed its behavior to be linear in practice over a wide range of programs. Further, it is quite fast, being competitive with a single run of all the above algorithms. The combined algorithm is much faster than the 2

or 3 iterations of all the above algorithms that a compiler requires in practice to reach a fixed point. We give timing and program improvement measurements in Chapter 5.

Our simple algorithm runs in time $O(n^2)$ because we have $O(n^2)$ variables and equations. The $O(n \log n)$ approach requires that our $O(n^2)$ equations and variables form an equivalence relation. The solution to the equations must form an equivalence relation at every major step and at the final answer. In our simple worklist algorithm, we solve equations in an arbitrary order determined by the worklist. This arbitrary order may not maintain an equivalence relation. However, if no uninitialized variables are being used then the final answer **will** be an equivalence relation (even if the intermediate steps are not). Portions of this algorithm deal with choosing an order for worklist processing that maintains an equivalence relation.

If the programmer uses an undefined (uninitialized) variable,¹⁶ then the equations may **not** form an equivalence relation in the final solution. This is because T is congruent to both 3 and 4, while 3 and 4 are not congruent. This solution is beyond our partitioning algorithm to represent, so we do not try: the algorithm breaks such congruences arbitrarily until it can form an equivalence relation. The final answer is a conservative approximation to the truth. We justify this by claiming that a programmer who relies on undefined variables is depending on undefined behavior; the language implementor (the compiler writer) may choose any answer he desires. We cover this in more detail in Section 4.4.

4.1.1 Equivalence Relations

We have to work to ensure our partial solutions always form an equivalence relation. We can do this by choosing a careful ordering during the worklist solution. However, if we always have an equivalence relation for our partial solutions we can represent the solution to many variables with a single solution for their partition.

We will start with Hopcroft's DFA minimization algorithm [28]. We present it here because a thorough understanding of it is required for what follows. We then present Alpern, Wegman and Zadeck's extensions that transform Hopcroft's algorithm into a Global Congruence Finding algorithm [2]. This algorithm discovers all the congruences of

¹⁶ Some languages initialize all variables to some known constant (like zero). From the compiler writer's point of view, such variables are defined.

the form: equal functions on congruent inputs. Next we add in elements from a constant propagation lattice: \top and \perp (no numbers yet). Any variable that computes \top is congruent to everything. We interleave \top/\perp propagation with the splitting algorithm. We then add the constants and constant congruences (*e.g.*, anything that computes 2 is congruent to everything else that computes 2). We also note that the subtract (compare, divide) of congruent values is zero (equal, one). Next, we add in the trivial COPY or identity function congruences. Then we add the algebraic identities, such as $x + 0$ and $x \times 1$. Finally, we add in *merge*, or \cap , -of-congruent-values congruences; the merge of x and x is x .

At each step we prove a running time of $O(n \log n)$. Because of the number of modifications, we will be showing changes to the algorithm underlined. Changes to the proof we will handle by presenting replacement paragraphs.

4.1.2 Notation

We cover our intermediate representation in detail in Appendix A. For now, we treat expressions in a program as Nodes in a graph. Variables in expressions become input edges in the graph. We use a special Node, the REGION, to represent basic blocks. Nodes have an input from the basic block (REGION) in which they reside. We treat this input like any other data input. The simplicity of our algorithm relies on this crucial detail: we treat control dependences just like data dependences. The algorithm makes no distinction between them. As a pleasant side effect, the algorithm handles irreducible loops.

Nodes and program variables are equivalent here, and are named with lowercase italic letters such as x and y . Partitions are sets of congruent Nodes and are named with uppercase italic letters, X and Y . The partition of x is $x.partition$. $X.any$ is any Node from partition X .

A program is a set of Nodes with a distinguished START Node. Nodes and expressions are equivalent here as well. The expression “ $x = y + z$ ” defines the Node x to have an ADD opcode and 2 inputs, from Nodes y and z . We denote the ADD opcode as $x.opcode$. We denote the i th input to Node x as $x[i]$; these inputs amount to use-def chains. Thus, $x[0]$ is y and $x[1]$ is z .

We also have the set of *def-use* chains, denoted $x.def_use$. We further subdivide them into def-use chains for each ordered input. Thus $x.def_use_0$ is the set of Nodes that use x on input 0. If $y \in x.def_use_i$, then $y[1]$ is x .

4.1.3 Implementation

In our implementation, each Node is a C++ object (*i.e.*, a C structure). The opcode field is the C++ class (implemented by the compiler as a hidden virtual function table pointer). The C equivalent would be an **enum** field. We encode the inputs as an array of pointers to Nodes; the opcode implicitly determines the size of the array. The inputs double as the use-def chains; we do not maintain a separate use-def data structure. This allows our algorithm to traverse use-def edges with a single array lookup.

We implement the def-use chains as a single large array of Node pointers. Each Node holds an internal pointer and the length of a subarray. A mirror array holds the reverse index number of each def-use pointer (*i.e.*, the use-def input number for which this def-use pointer is the reverse of). We build this dense structure with two passes over the use-def edges before running the combined optimization algorithm. It allows efficient iteration over the def-use chains.

4.2 Hopcroft's Algorithm and Runtime Analysis

In this section we discover:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.

We show Hopcroft's algorithm here [28]. We modify the presentation slightly to better fit our problem. In particular, we need to be very precise about where and when we count work in the algorithm. As done in Alpern, Wegman, and Zadeck [2] we use a program graph instead of a DFA. We use *ordered* edges instead of the usual DFA notation of transition symbols from some alphabet. Instead of a final state, we will use the Program's START Node. The resulting algorithm partitions the program Nodes into congruence classes. Two Nodes are congruent if they compute equal functions and if their ordered inputs come from the same congruence class.

```

Place all Nodes in partition  $X$ .
Split partition  $X$  by opcode.
Place all partitions on worklist.
While worklist is not empty, do
    CAUSE_SPLITS( worklist );

```

We will use a helper function to split partitions. Its main purpose is to ensure that when the algorithm splits a partition, the newly created partition is on the *worklist* if the original partition is.

```

Partition SPLIT( Partition  $Z$ , Set  $g$  ) {
    Remove  $g$  from  $Z$ .
    Move  $g$  to a new partition,  $Z'$ .
    If  $Z$  is on worklist then add  $Z'$  to worklist.
    Else add the smaller of  $Z$  and  $Z'$  to worklist.
    Return  $Z'$ .
}

```

We maintain the following invariants between calls to CAUSE_SPLITS:

- All partitions are well formed: every Node is in exactly 1 partition, each partition has an accurate count of members, and no partition is empty.
- The *worklist* accurately reflects splitting that may need to occur: in any one partition X , for all inputs i , the set of partitions represented by $\{\forall x \in X, x[i].partition\}$ has at most one partition not on the *worklist* (i.e., there are not two Nodes in X that get their i th inputs from different partitions, without at least one of those partitions being on the *worklist*).

```

1. CAUSE_SPLITS( worklist ) {
2.     Remove a partition  $X$  from worklist.
3.      $\forall$  inputs  $i$  do {
4.         Empty the set of touched partitions, touched.
5.          $\forall$  Nodes  $x$  in partition  $X$  do {
6.              $\forall$  Nodes  $y$  in  $x.def\_use_i$  do {
7.                 Add  $y.partition$  to touched.
8.                 Add  $y$  to the set  $y.partition.touched$ .
9.             }
10.        }
11.     $\forall$  partitions  $Z$  in touched do {
12.        If  $|Z| \neq |Z.touched|$  then do
13.            SPLIT(  $Z$ ,  $Z.touched$  )
14.        Empty  $Z.touched$ .
15.    }
16. }
17. }

```

Figure 4.1 Partition X causing partition Z to split

Crucial to the running time is the inverted sense of *worklist*. *Worklist* does not hold partitions that need splitting. Instead, it holds partitions that have recently split and thus may cause other partitions to split. In Figure 4.1, the algorithm just pulled partition X from the worklist. Following the def-use edges back from the Nodes in X touches all the Nodes in Y, but only some in Z. In line 12, $|Y|$ will be equal to $|Y.touched|$, so Y does not need splitting. Not so for Z, which splits along the dotted line. The smaller Z split goes on the *worklist*.

In line 13 we see that if a Node is part of a partition that is already on the *worklist*, after splitting the partition, the Node will still be in a partition on the *worklist*. However, we observe that a Node can be placed on the *worklist* at most $O(\log n)$ times (it may be part of a splitting partition up to $O(n)$ times). This is because SPLIT moves the smaller partition onto the worklist. The Node is in a partition of at most $1/2$ the size it was in the last time it moved from off to on the *worklist*.

Each time we pull a partition from the *worklist*, we must do work proportional to all the def-use edges (lines 3, 5 and 6). However, we take care not to do more than this much work. Thus we **spend** work when we follow a partition's def-use edges. Through careful use of data structures, we only do a constant amount of work per edge. The algorithm visits each edge once per time the edge's defining Node's partition is pulled from the *worklist*, or $O(\log n)$ times. There are $O(n)$ edges; total running time is $O(n \log n)$.

We still must show that we only do a constant amount of work per def-use edge visit. Clearly lines 7 and 8 execute once per edge and can be accomplished in $O(1)$ time. In

lines 12 and 14 at most 1 partition per edge is in *touched* and each line can happen in $O(1)$ time. The total of all Nodes moved from one partition to another in line 13 cannot be more than the number of Nodes visited in lines 7 and 8, and again the moving itself can happen in constant time.

4.2.1 Implementation

We implement the partitions as structures with a doubly linked list of Nodes for members; constant time list removal being required in line 13. The algorithm maintains a count of members for the tests in SPLIT and line 12. We implemented the *worklist* and *touched* sets as singly linked lists of partitions, with an extra flag bit to perform the constant-time membership test needed in SPLIT and line 7. The *X.touched* set was also implemented as a singly linked list, again with a member count for the line 8 test.

4.3 Adding Unreachable Code Elimination

In this section we discover:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.
2. Two PHI Nodes are congruent if their ordered inputs are congruent, ignoring inputs from unreachable paths.
3. The type of each Node, as an element from the lattice $\{\mathcal{U}, \mathcal{R}\}$. Types are determined by function and input types.

Nodes hold lattice elements, called *types*, that represent an approximation to the set of values a Node can take at runtime. We refer to the type of a Node x with $x.type$. We are adding in just the reachability lattice $\mathcal{L}_u \{\mathcal{U}, \mathcal{R}\}$. REGION, IF, JUMP, and START Nodes compute values from this lattice. The integer lattice will be added in the next section. For now, the remaining nodes compute a data value and will have their type fields set to \perp .

In Chapter 3 we represented reachability with a variable per statement. In this chapter we present a more convenient method; reachability is computed per basic block and unreachable computations are ignored at PHI Nodes. We use REGION Nodes to represent basic blocks; the type at a REGION Node determines whether the block is reachable or not.

Two PHI Nodes are congruent if they have the same REGION Node input (occur in the same basic block) and their ordered reachable inputs are congruent. In the code that follows, the unreachable inputs are ignored and the two PHI Nodes are congruent:

```

 $x_0 := y_0 := \text{read}();$     // Read some unknown value
if( False ) {              // A condition that is never true
     $x_1 := 2;$                 // Unreachable code
     $y_1 := 3;$                 // Unreachable code
}
 $x_2 := \phi( x_0, x_1 );$       // Merge  $x_0$  and an unreachable value
 $y_2 := \phi( y_0, y_1 );$     // Merge  $y_0$  and an unreachable value

```

Since unreachable values are ignored, the Nodes computing those values are useless. A round of dead code elimination will remove them. This dead code elimination is incorporated in the transformation phase of the algorithm, presented in section 4.10.

We do not want any values from unreachable paths causing a partition of PHIs to split. So we allow PHI Nodes to ignore inputs from unreachable paths when determining congruence. In the algorithm CAUSE_SPLITS we insert a test between lines 6 and 7:

```

6.       $\forall$  Nodes  $y$  in  $x.\text{def\_use}_i$  do {
6.5      If  $y$  is not a PHI or input  $i$  is a live path into  $y$  then do {
7.          Add  $y.\text{partition}$  to  $\text{touched}$ .
8.          Add  $y$  to the set  $y.\text{partition.touched}$ .
8.5      }
9.      }

```

4.3.1 Accounting for work during Conditional Constant Propagation

The sparse CCP algorithm of Wegman and Zadeck runs in linear time [49]. As presented in section 3.5, we count work by **edge visits**. The algorithm visits a use-def edge once each time the defining Node drops in the lattice (once in our case). Each edge visit causes a constant time evaluation of the using Node's type. We may also have to do a constant amount of work adding or removing the Node's partition from the *cprop* work-list.

The same work analysis will hold when we interleave the propagation and the partitioning algorithms. The major difference will be the order of visitation: we will propagate types *within* a partition until the partition stabilizes before we propagate types outside a partition. In addition, we will split partitions by type, so within a partition (and between

calls to PROPAGATE) all Nodes will have the same type. This will require us to have a local constant propagation worklist per partition, implemented as a doubly linked list with a bit flag for constant time membership tests. We refer to this local worklist for partition X as $X.cprop$. When a Node falls in the lattice we put it in a *fallen* set. After propagation stabilizes, we split the *fallen* set from the original partition.

```

1. PROPAGATE( cprop ) {
2.   While cprop is not empty do {
3.     Remove a partition  $X$  from cprop.
4.     While  $X.cprop$  is not empty do {
5.       Remove a Node  $x$  from  $X.cprop$ .
6.       Compute a new type for  $x$ .
7.       If  $x$ 's type changed then do {
8.         Add  $x$  to fallen.
9.          $\forall$  Nodes  $y$  in  $x.def\_use$  do
10.          Add  $y$  to  $y.partition.cprop$ .
11.       }
12.     }
13.     Let  $Y$  be
14.       If  $|fallen| \neq |X|$  then SPLIT(  $X, fallen$  ) else  $X$ .
15.     SPLIT_BY(  $Y$  ).
16.   }
17. }
```

4.3.2 The modified algorithm

```

Place all Nodes in partition  $X$ .
Split partition  $X$  by opcode.
Place all partitions on worklist.
Initialize all Nodes' type to  $\mathcal{U}$  or  $\perp$ .
Place the START Node's partition on cprop.
Place the START Node on its local worklist.
Do until worklist and cprop are empty {
  PROPAGATE( cprop );
  If worklist is not empty, then
    CAUSE_SPLITS( worklist );
}
```

We maintain the following invariants between and after iterations of PROPAGATE, with the underlining indicating new invariants:

- All partitions are well formed: every Node is in exactly 1 partition, each partition has an accurate count of members, and no partition is empty.
- The *worklist* accurately reflects splitting that may need to occur: in any one partition X , for all inputs i , the set of partitions represented by $\{\forall x \in X, x[i].partition\}$

has at most one partition not on the *worklist* (i.e., there are not two Nodes in X that get their i th inputs from different partitions, without at least one of those partitions being on the worklist).

- Within a partition, all Nodes have the same type.
- The local *cprop* worklist accurately reflects type propagation that may need to occur: the type of every Node in the partition is its function on the current inputs, or the Node is on the *cprop* worklist.
- All partitions with Nodes on their local *cprop* worklist are on the global *cprop* worklist.

4.4 Adding in Constant Propagation

In this section we discover:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.
2. Two PHI Nodes are congruent if their ordered inputs are congruent, ignoring inputs from unreachable paths.
3. The type of each Node, as an element from the $\{\mathcal{U}, \mathcal{R}\}$ lattice or the $\{\mathbf{T}, \mathbf{Z}, \perp\}$ lattice. Types are determined by function and input types.
4. Two Nodes are congruent if either Node computes \mathbf{T} .

We are adding in both the reachability lattice $\mathcal{L}_u \{\mathcal{U}, \mathcal{R}\}$ and the constant propagation lattice $\mathcal{L}_c \{\mathbf{T}, \mathbf{Z}, \perp\}$. We treat them identically. Since the different values appear in disjoint kinds of Nodes, we use the same representation for both \mathbf{T} and \mathcal{U} . We distinguish them by the Node opcode. In this algorithm we never need to make this distinction.

Figure 4.2 The modified equivalence relation

We want type T to be congruent to everything. We use a modified equivalence relation to represent these congruences. The *implementation* uses a real equivalence relation, with a special partition named TOP . A Node is in TOP if and only if it computes T . When determining if two Nodes are congruent we use a 2-step test: either one of the Nodes is in TOP or both are in the same normal partition. In Figure 4.2, Nodes a and b are congruent because they are both in partition X . Nodes a and c are congruent because c is in TOP and so computes T . Nodes a and d are not congruent, although c and d are. Thus, the congruence relation is not transitive. We maintain the invariant that within a partition, every Node computes the same type.

In this limited framework, splitting a partition never causes a Node's type to fall from T to \perp . We can solve this simple combined problem with a phase-order solution: propagate all the types before finding congruences. However, we will be introducing mixing functions in the next section where interactions between a Node's type and partition are possible. Thus in this section we will interleave constant propagation and congruence finding (partition splitting). The extensions to support more complex approximation functions will then be fairly simple.

Since Nodes that compute T are all congruent, we do not require an initial split by function. Instead, as Nodes fall from the T lattice element and are removed from the TOP partition, we will be require to split by function and inputs.

After we have lost the congruences due to T and split by type, we need to make our partitions have a uniform function and preserve the *worklist's* splitting invariant. Therefore we will split the partitions again by opcode and inputs. We do this splitting only

when a Node falls in the lattice, *i.e.*, only once per Node. The splitting is done in time proportional to the number of inputs to all Nodes involved. Since this happens only once per Node, total time is $O(E)$. The following code first splits by type, then if the partition is not *TOP*, it also splits by opcode and inputs.

```

1. SPLIT_BY( Partition X ) {
2.   Let  $P$  be the set of partitions returned by
3.   SPLIT_BY_WHAT(  $X, \lambda n.(n.type)$  ).
4.    $\forall$  partitions  $Y$  in  $P$  do {
5.     If  $Y.type$  is not  $T$  then do {
6.       Let  $Q$  be the set of partitions returned by
7.       SPLIT_BY_WHAT(  $Y, \lambda n.(n.opcode)$  );
8.        $\forall$  partitions  $Z$  in  $Q$  do
9.          $\forall$  inputs  $i$  do
10.          SPLIT_BY_WHAT(  $Z, \lambda n.(n[i].partition)$  );
11.     }
12.   }
13. }
14.
15. SPLIT_BY_WHAT( Partition  $X$ , function  $What(Node)$  ) {
16.   Let  $map$  be an empty mapping from the range of  $What$  to sets of Nodes.
17.    $\forall$  Nodes  $x$  in  $X$  do {
18.     If  $What(x) \notin map$  then do
19.       Add the  $\{What(x) \rightarrow \text{a new empty set of Nodes}\}$  mapping to  $map$ .
20.     Add  $x$  to  $map[What(x)]$ .
21.   }
22.   Let  $P$  be a set of Partitions.
23.    $\forall$  sets  $S$  except one in the range of  $map$  do
24.     Add SPLIT(  $X, S$  ) to  $P$ .
25.   Add  $X$  to  $P$ .
26.   return  $P$ .
27. }
```

In the call to SPLIT_BY_WHAT in line 10, SPLIT_BY_WHAT($Z, \lambda n.(n[i].partition)$), it is **crucial** that the splitting occurs before Nodes move into their new partitions. If we call $What(x)$ after we have moved some Nodes into their new partitions, $What(x)$ will return the new, not the old partition. This will break cycles of congruences occurring within the original partition.

Note that Nodes with equal functions and congruent inputs will always compute the same type. In order for them not to compute the same type, the congruent inputs must not be computing the same type. By a simple induction argument, there must be a first time when congruent inputs are not computing the same type. But we split partitions by

type, so that all Nodes in a partition have the same type. For the inputs to be congruent but with different types, one of the types must be T. However, data nodes with a T input always compute T and so would be congruent in any case. The more interesting case of PHI Nodes is discussed in the next section.

4.4.1 PHI Nodes and T

T propagates through all data computations, so if any data node has a T input, it computes T. Only PHI and REGION Nodes can have a T input and not compute T.

With a naive evaluation order between constant propagation steps and splitting steps, it is possible to reach the problematic situation shown in Figure 4.3: one partition with 3 PHIs using the same REGION. x_3 merges input 1 from partition X, y_3 merges input 1 from Y and z_3 merges input 1 from TOP. Suppose we remove partition X from the *worklist* and we follow its def-use chains. We will only touch x_3 . When we split x_3 from y_3 we must decide what to do with z_3 . Since Nodes in TOP are congruent to Nodes in both X and Y, we would like z_3 to be congruent to both x_3 and y_3 (equal functions on congruent input rule). Unfortunately, this is beyond our framework to represent.

Figure 4.3 Splitting with “top”

We prevent this problem by propagating Ts before we split partitions. By postponing splitting until types are resolved, we avoid the issue. It is not possible to bring in a T value along a reachable path to a PHI without using an uninitialized variable. It is still possible to bring a T value along an unreachable path, but PHI Nodes ignore unreachable inputs.

The problematic situation can still arise if we **must** bring a T into a PHI Node (and the problem is only interesting if the path bringing the T in is reachable). This can only occur

when the program actually uses an undefined value.¹⁷ We arbitrarily break a congruence and stick z_3 with y_3 . Since the semantics of using an undefined value are undefined, breaking a congruence is a safe and conservative solution. It is not, however, the optimal solution. The problematic code, in SSA form, follows:

```

int x0, y0, z0;           // x0, y0, z0 are all undefined here
if( pred() ) {              // Some unknown predicate
    t := read();             // Assign t with a keyboard read
    x1, y1, z1 := t;        // Make x, y, and z all congruent
} else {
    x2 := read();           // Assign x and y with different values
    y2 := read();           // z is left undefined
}
x3 := φ( x1, x2);         // Merge x1 and x2
y3 := φ( y1, y2);         // Merge y1 and y2
z3 := φ( z1, z0);         // Merge z1 and z0; z0 has type T

```

The *TOP* partition itself never needs to be split because some inputs changed partitions (it will be split when Nodes drop from T to some non-T type). Nodes in the *TOP* partition are congruent because they compute T, irrespective of whether they also compute the same function on congruent inputs. This leads us to modify CAUSE_SPLITS again:

```

6.      ∀ Nodes y in x.def_usei do {
6.1      Let Y be y.partition.
6.5      If Y is not TOP and (y is not a PHI or input i is a live path into y) then {
7.          Add Y to touched.
8.          Add y to the set Y.touched.
8.5      }
9.      }

```

4.4.2 The modified algorithm

We can now place all Nodes in the same initial partition, and rely on splitting work done by PROPAGATE to do the splitting by opcode. The modified main loop is now:

```

Place all Nodes in partition X.
Initialize all Nodes' type to  $\mathcal{U}$  or T.
Place the START Node's partition on cprop.
Place the START Node on its local worklist.
Do until worklist and cprop are empty {
    PROPAGATE( cprop );
    If worklist is not empty, then
        CAUSE_SPLITS( worklist );
}

```

¹⁷ The problem appeared at least a dozen times in the 52 routines I tested.

4.5 Allowing Constants and Congruences to Interact

In this section we discover the following facts about a program:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.
2. Two PHI Nodes are congruent if their ordered inputs are congruent, ignoring inputs from unreachable paths.
3. The type of each Node, as an element from the $\{\mathbb{Z}, \mathbb{R}\}$ lattice or the $\{\top, \mathbb{Z}, \perp\}$ lattice. Types are determined by function and input types.
4. Two Nodes are congruent if either Node computes \top or they both compute the same constant.

Any two Nodes that compute the same constant are congruent, regardless of how they compute that constant. In addition to the integer constants, we can extend the type lattice in many directions. We present just the integer constants, but our implementation includes ranges of integer constants with strides, floating-point and double precision constants, and code address labels. These extra types do not require changes to the algorithm. The only changes required are in the approximation functions (*meet*, etc.).

Partitions of constants should not be split simply because their Nodes have unequal functions or incongruent inputs. We need to change CAUSE_SPLITS to reflect this:

```

6.5      If y.type is neither  $\top$  nor constant and
          (y is not a PHI or input i is a live path into y) then do {

```

After propagation stabilizes, we split by types. Then SPLIT_BY splits by function and inputs. Again we do not want to split partitions of constants, so we modify SPLIT_BY:

```

5.      If Y.type is below  $\top$  and all constants then do {

```

Nodes that fall from constants to \perp (or other non-constant types such as ranges) are handled in the PROPAGATE code when the *fallen* set is passed to SPLIT_BY.

4.6 Subtract and Compare

So far we allow constants to affect congruences (by not splitting partitions of constants, even when they have different functions or inputs). Here we allow mixing of information in the reverse direction: the subtraction of congruent values is zero. The same behavior is applied to compare and T.¹⁸ This inference is fundamentally different than the previous inferences, because we are allowing a congruence inference to affect a constant inference. If we lose that congruence inference by splitting a partition which is being used on both inputs to a SUB Node then we need to reevaluate the SUB Node's type.

Since at least one of the two inputs to the SUB Node must end up on the *worklist*, we will be visiting the SUB Nodes during the course of a future splitting operation. Thus, during splitting operations we can place each Node visited along a def-use chain on the local *cprop* worklist. This requires only a constant amount of work (put on worklist, take off worklist, and check the type) per Node, an amount of work we already pay for just to follow the def-use chain. This requires an extra visit for every Node involved in a split. Instead, we only require SUB and COMPARE Nodes to have an extra visit:

```

6.1      Let Y be y.partition.
6.2      If y.type is constant and y has opcode SUB or COMPARE then do
6.3          Add y to Y.cprop.
```

One final difficulty: when we propagate constants through the *TOP* partition, it is possible to bring unequal constants into a SUB Node still within *TOP*. As shown in Figure 4.4, the approximation function for SUB has a dilemma; it can either subtract congruent inputs and compute 0, or it can subtract constant inputs for a constant result.

In this case the two inputs to SUB can never be congruent in the final answer. We can show this with an induction proof; there is never a first time that two Nodes compute unequal constants while remaining congruent. They will eventually be split. SUB should subtract the constants. We give C++ code for a subtract Node's approximation function below:

¹⁸ We can also define x/x to be 1. This defines $0/0$ as 1, a questionable choice. Discovering x/x to be 1 is unlikely to significantly impact many programs.

```

SubNode::Compute() {
    const Type *t1 := in1→type;           // Quick access to input type
    const Type *t2 := in2→type;           // Quick access to input type
    if( t1 = Type_Top || t2 = Type_Top )   // If either input is undefined
        type := Type_Top;                 // ...then so is the result
    else if( t1→is_con() && t2→is_con() )   // If both inputs are constants
        type := Type(t1→get_con() - t2→get_con()); // ...then compute the result
    else if( in1→part = in2→part )         // If the inputs are congruent
        type := Type_0;                   // ...then the result is 0
    else                                   // Otherwise, the result is not
        type := Type_Bottom;              // ...a compile-time constant
}

```

Figure 4.4 Does SUB compute 0 or 1?

4.7 Adding the Identity Function Congruences

In this section we show how the algorithm can find these facts:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.
2. Two PHI Nodes are congruent if their ordered inputs are congruent, ignoring inputs from unreachable paths.
3. The type of each Node, as an element from the $\{\mathcal{N}, \mathcal{R}\}$ lattice or the $\{\mathbf{T}, \mathbf{Z}, \perp\}$ lattice. Types are determined by function and input types.
4. Two Nodes are congruent if either Node computes \mathbf{T} or they both compute the same constant.
5. Two Nodes are congruent if one is a COPY of the other.

We allow Nodes to be *copies* of one another by using the identity function or COPY opcode. These arise from program assignments, compiler temporaries, register-to-register moves and the like. They are also a stepping stone to more complex algebraic identities like $x + 0$ and $x \times 1$.

4.7.1 Leaders and Followers

We introduce a notion of Leaders and Followers.¹⁹ Partition Leaders are nodes in a partition that directly compute a value. Followers are congruent to some Leader through a string of algebraic identities; initially we only allow COPY. We keep Leaders and Followers in the same partition in separate sets. We refer to just the Follower Nodes of partition X as $X.Follower$, and the Leader Nodes as $X.Leader$. In the *TOP* and constant partitions the distinction is not important since the type congruences subsume the identity congruences. In these partitions, the algorithm treats all Nodes as Leaders.

When Nodes fall from T or constants to non-constants, the distinction becomes important. We do an initial split of the Nodes into Leaders and Followers. Afterwards, Nodes can make the Follower \Rightarrow Leader transition only once and each transition is done in constant time, so all transitions take no more than $O(n)$ time. However, we must account for the transition tests more carefully. For our initial case, COPYs remain as Followers and all others become Leaders when they first fall from T /constant to non-constant types. This requires a constant-time test once per Node, or $O(n)$ time.

Previously, when we walked the def-use chains in CAUSE_SPLITS, we were trying to discover if we touched only some of a partition's Nodes. We now want to know if we touch only some of a partition's Leaders. If we touch all the Leaders (and any number of Followers), then the Followers will follow the Leaders and the partition does not need splitting. In Figure 4.5 we do not need to split partition Y , despite only some of Y 's Nodes being reached from def-use chains out of X .

When we follow the def-use chains of Nodes in X , we need to follow edges leaving both Leader and Follower Nodes in X . However, we do not want to cause splitting because we touched some Followers. Followers remain congruent by some algebraic identity (regardless of the equal-functions-on-congruent-inputs rule). We split the set of def-use edges into a set of edges leading to Followers and a set of edges leading to Leaders.

¹⁹ No relation to Tarjan's disjoint-set Union-Find algorithm.

Figure 4.5 No splitting required in partition *Y*.

4.7.2 The Race

Previously when we split a partition in two, we placed the smaller piece on the worklist. This choosing of the smaller piece is critical to the $O(n \log n)$ running time. It limits Nodes to being in partitions of at most $1/2$ the size they were in the last time the Nodes moved onto the *worklist*. We must count size correctly, counting both Leaders and Followers. After touching only some Leaders, we must determine whether the touched Leaders plus their Followers is larger or smaller than the untouched Leaders and remaining Followers. This requires that we discover how many Followers are behind each Leader.

When we split, the Nodes moving into the split must all be touched to change their partition. The piece with the smaller number of Leaders may have up to $O(n)$ Followers, and touching them all would be disastrously slow. Instead we must only move Nodes from the smaller piece into the new partition. Previously, we did work proportional to the number of Leaders touched, which was always at least as large as the smaller split. We still must do no more work than the smaller split.

We must discover which piece of the split is smaller without visiting the entire partition. To do this, we hold a race. We walk the def-use chains back from the Leaders in the two original sets, counting Followers. We alternate, counting a Node first from one side, then the other. When one side runs out of Followers, we declare it the winner. We touch every Node in the smaller piece once and touch an equal number of Nodes in the larger piece. We end up touching no more than twice the Nodes in the smaller piece. In Figure

Figure 4.6 Racing the halves of partition Y .

4.6, the right hand side of Y wins the race (and is the smaller of the two splits), despite the left hand side having only one Leader.

Considering only the COPY identities, we can hardly justify the race notion. We could remove the COPY Nodes with a single pass over the program graph, mapping uses of COPS into uses of the COPS' inputs. However, when we have a more complex notion of when something is a Follower and when it is not, the race idea elegantly solves the problem of determining who follows which Leader.

The race code itself maintains some state so that it can alternate a breadth-first search between two subgraphs. The *initial* sets represent Leader Nodes not yet visited. While we have already spent time proportional to $|g|$ (and so we can spend it again in line 2), we cannot spend time proportional to $|X.Leader-g|$. This means we cannot enumerate set h in line 2. We use a doubly linked list to implement $X.Leader$. In time $O(|g|)$ we visit and remove g from $X.Leader$ and call the result h . This result is used in line 8. We can regenerate the $X.Leader$ set by pasting g and h together.

The *unwalked* sets represent Nodes whose Follower def-use edges are not yet walked. The first Node of an *unwalked* set is partially walked, with *index* def-use edges already visited. *Walked* Nodes have all Followers that were following them moved into either *walked* or *unwalked*. Because the Follower Nodes will form DAGs and cycles (instead of just the simple trees possible now) we need a flag to determine if we have already visited a Node.

```

1. Partition SPLIT( Partition  $X$ , Set  $g$  ) {
2.   Let  $h$  be  $X.Leader - g$ .
3.   Make new empty Sets  $unwalked_1$ ,  $unwalked_2$ .
4.   Make new empty Sets  $walked_1$ ,  $walked_2$ .
5.   Let  $index_1$  and  $index_2$  be 0.
6.   Forever do {
7.     If STEP( $g$ ,  $unwalked_1$ ,  $walked_1$ ,  $index_1$ ) then Let  $winner$  be 1; break loop;
8.     If STEP( $h$ ,  $unwalked_2$ ,  $walked_2$ ,  $index_2$ ) then Let  $winner$  be 2; break loop;
9.   }
10.  Clear flags from  $unwalked_1$ ,  $walked_1$ ,  $unwalked_2$ ,  $walked_2$ .
11.  Subtract  $walked_{winner}$  from  $X$ .
12.  Move  $walked_{winner}$  to a new partition,  $X'$ .
13.  If  $X$  is on worklist then add  $X'$  to worklist.
14.  Else add the smaller of  $X$  and  $X'$  to worklist.
15.  return  $X'$ .
16. }
17.
18. Boolean STEP( Set  $initial$ , Set  $unwalked$ , Set  $walked$ ,  $index$  ) {
19.   If  $initial$  is not empty then do {
20.     Move any Node from  $initial$  to  $unwalked$ .
21.     Return False.
22.   }
23.   While  $unwalked$  is not empty do {
24.     Let  $n$  be the first Node in  $unwalked$ .
25.     While  $index < |n.F.def\_use|$  then do {
26.       Let  $m$  be  $n.F.def\_use[index]$ .
27.       Add 1 to  $index$ .
28.       If  $m$  is not flagged then do {
29.         Flag  $m$ .
30.         Add  $m$  to  $unwalked$  not as first Node.
31.       }
32.     }
33.   }
34.   Move  $n$  to  $walked$ .
35.   Reset  $index$  to 0.
36. }
37. return True.
38. }

```

4.7.3 Counting work

During splitting we do work proportional to the larger of: the number of Leaders touched and the smaller of the split pieces. Previously we linked these two quantities. Now however, we may have many Followers in a partition with few Leaders. We must count work for the two quantities separately.

When we split, we can do no more than work proportional to the smaller partition. The smaller split may be much larger than the number of Leaders touched, but this does not matter. Instead we rely on the argument that each time the algorithm involves a Node

in a split, the Node ends up in a partition of at most $1/2$ the size it used to be. Thus the algorithm cannot involve a Node in a split more than $O(\log n)$ times, for a total splitting cost of $O(n \log n)$.

When we run the race, we cannot spend time on def-use edges that do not lead to Followers (*e.g.*, edges that leave the partition). This is because we cannot use more than a constant amount of time to find the next Follower during each step of the race, but there may be $O(n)$ def-use edges from a single Leader to Nodes in other partitions. This requires us to segregate our def-use edges into edges that lead to Followers in this partition and edges that lead to other Nodes.

4.7.4 Implementation

Our implementation stores the def-use edges in a subarray, with the base and length kept in each Node. We keep the array sorted with Follower edges first, then Leader edges. We also keep the length of the Follower edge set; we compute the Leader edge set size from the difference. We use the notation $x.def_use$ to represent the set of def-use edges for a Node x , $x.L.def_use$ for edges leading to Leaders, $x.F.def_use$ to represent edges leading to Followers of x , and $x.other.def_use$ for edges leading to Followers in other partitions. This last set is empty right now, but later this set will hold edges leading from constants to algebraic 1-constant-input identities such as the ADD of 0. Each Node has a constant time test to determine if it is a Follower (for now, the test is “ $x.opcode = COPY$ ”).

4.7.5 The modified algorithm

Because of the number of changes, we present the complete altered routines in Figure 4.7. As before, changes are underlined.

```

1.  PROPAGATE( cprop ) {
2.      While cprop is not empty do {
3.          Remove a partition X from cprop.
4.          Let oldtype be X.type.
5.          While X.cprop is not empty do {
6.              Remove a Node x from X.cprop.
7.              Compute a new type for x.
8.              If x's type changed then do {
9.                  Add x to fallen.
10.              $\forall$  Nodes y in x.def_use do
11.                 Add y to y.partition.cprop.
12.             }
13.         }
14.         Let Y be
15.             If  $|fallen| \neq |X|$  then SPLIT( X, fallen ) else X.
16.         If oldtype was T or constant then do
17.              $\forall$  Nodes y in Y do
18.                 If y is not a constant and y is a Follower then do {
19.                     Move y to Y.Follower.
20.                     Segregate the def-use chains leading to y into L/F edges.
21.                 }
22.             SPLIT_BY( Y ).
23.         }
24.     }
25.
26. CAUSE_SPLITS( worklist ) {
27.     Remove a partition X from worklist.
28.      $\forall$  inputs i do {
29.         Empty the set of touched partitions, touched.
30.          $\forall$  Nodes x in partition X.Leader+X.Follower do {
31.              $\forall$  Nodes y in x.L.def_usei do {
32.                 Let Y be y.partition.
33.                 If y.type is constant and y has opcode SUB or COMPARE then do
34.                     Add y to Y.cprop.
35.                 If y.type is neither T nor constant and
36.                     (y is not a PHI or input i is a live path into y) then do {
37.                     Add Y to touched.
38.                     Add y to the set Y.touched.
39.                 }
40.             }
41.         }
42.          $\forall$  partitions Z in touched do {
43.             If  $|Z.Leader| \neq |Z.touched|$  then do
44.                 SPLIT( Z, Z.touched )
45.             Empty Z.touched.
46.         }
47.     }
48. }

```

Figure 4.7 The algorithm, modified to handle *Leaders* and *Followers*

4.8 The Algebraic, 1-Constant Identities: $x + 0$ and $x \times 1$

In this section we discover:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.
2. Two PHI Nodes are congruent if their ordered inputs are congruent, ignoring inputs from unreachable paths.
3. The type of each Node, as an element from the $\{\mathcal{U}, \mathcal{R}\}$ lattice or the $\{\mathcal{T}, \mathcal{Z}, \perp\}$ lattice. Types are determined by function and input types.
4. Two Nodes are congruent if either Node computes \mathcal{T} or they both compute the same constant.
5. Two Nodes are congruent if one is an algebraic, 1-constant identity on the other. Algebraic, 1-constant identities are identities such as $x + 0$, $x - 0$, $x \times 1$, $x \div 1$, x or 0 , x and $0xFFFFFFFF$, $\text{MIN}(x, \text{MAXINT})$, $\text{MAX}(x, \text{MININT})$, and the like.

We allow Nodes to be congruent if one is an algebraic, 1-constant identity on the other. Algebraic, 1-constant identities are 2-input functions where when one input is a special constant (determined on a per-opcode basis) then the function is an identity on the other input. If y is an algebraic identity of x then at least 1 input to y must be from x 's partition (later we allow more).

We do not require the special constants (commonly 0 or 1) to be literal constants. They may be computed or congruent to 0 or 1. In particular, $x + \mathcal{T}$ is congruent to x , since \mathcal{T} is congruent to 0; also $x + \mathcal{T}$ computes \mathcal{T} and so is congruent in any case. These congruences remain until the algebraic identity breaks when we lose the constant.

We have two new problems to support these congruences. The first is that we can lose the congruence. This implies that a Node can make the Follower \Rightarrow Leader transition. The algorithm has to adjust the lists and sets accordingly. The other problem is detecting when a Node needs to make that transition.

We only need to check for Follower Nodes losing their special constant when that input falls in the lattice. This check is a constant amount of work, which we are already paying for because we need to check the Node's type as well. We make a small change to PROPAGATE:

6. Remove a Node x from $X.cprop$.
- 6.1 If x is a Follower and is not an identity then do ...
7. Compute a new type for x .

Once we decide to make x a Leader we need to move it from the Follower set to the Leader set, update the def-use edges leading up to it and check for possible splitting. We add the set of Nodes that changed from Follower to Leader to the *fallen* set. This set contains Nodes that do not have the same type or opcode as the other Leaders in partition X .

4. Let *oldtype* be $X.type$.
- 4.1 Let *oldopcode* be $X.opcode$.
5. While $X.cprop$ is not empty do {
6. Remove a Node x from $X.cprop$.
- 6.1 If x is a Follower and is not an identity then do {
- 6.2 If $x.opcode$ is not *oldopcode* then add x to the *fallen* set
- 6.3 Move x from $X.Follower$ to $X.Leader$.
- 6.4 Make all inputs to x from inside X no longer be $F.def_use$ edges.
- 6.9 }
7. Compute a new type for x .

Adding X to *worklist* here handles any possible splitting problems. We have an edge internal to X leading to the new Leader x . The algorithm would touch x when it follows the def-use edges inside X . Touching x but not the other Leaders of X will split X . However, X could be quite large; placing all of X on the *worklist* will destroy our counting argument (Nodes enter the *worklist* in a partition of $1/2$ the size they last entered the *worklist*). Instead, we only place those Nodes that dropped in the lattice on the *worklist*. Since Nodes can only drop twice, this adds 2 extra times a Node can come off the *worklist*. Thus a Node can exit the *worklist* at most $O(2 + \log n)$ times. Since we do all constant propagation possible before returning to splitting-on-inputs, any Nodes that need to make the Follower to Leader transition get the opportunity to do so before we need to split them by inputs. We need one more change to PROPAGATE:

16. If *oldtype* was T or constant then do
- 16.5 Add Y to *worklist*.
17. \forall Nodes y in Y do

4.9 The Algebraic 2-Congruent-Input Identities: PHI and MAX

In this section we discover:

1. Two Nodes are congruent if they compute equal functions on ordered congruent inputs.
2. Two PHI Nodes are congruent if their ordered inputs are congruent, ignoring inputs from unreachable paths.
3. The type of each Node, as an element from the $\{\mathcal{N}, \mathcal{R}\}$ lattice or the $\{\mathcal{T}, \mathcal{Z}, \perp\}$ lattice. Types are determined by function and input types.
4. Two Nodes are congruent if either Node computes \mathcal{T} or they both compute the same constant.
5. Two Nodes are congruent if one is an algebraic, 1-constant identity on the other.
6. Two Nodes are congruent if one is an algebraic, 2-congruent-input identity on the other. Algebraic, 2-congruent-input identities include meet (or PHI or \cap), MAX, and MIN.

We allow the meet (max, min) of two congruent values to be congruent to both values. This is of special importance to the PHI functions, where we observe many of these identities in practice.

If x is congruent to y and “ $z = \phi(x, y)$ ” then z is congruent to both x and y . This 3-way congruence depends on x and y remaining congruent. When the x - y congruence breaks, so must the x - z and y - z congruences. Since z has more than 1 input from the same partition, we can build up large complex structures, including cycles, of PHI functions that remain congruent. We observe these in practice for any program with more than a moderate amount of control flow, so they must be handled efficiently.

Our greatest difficulty comes when we split partitions. The very act of splitting a partition will break these congruences, turning these Nodes from Followers to Leaders and setting off another wave of splitting. In Figure 4.8, ϕ_1 needs to go with the left partition, and ϕ_3 and ϕ_4 belong with the right partition. The node ϕ_2 can go with either half, as long as we convert it from a Follower to a Leader. One of the two splits will go on the *worklist*, and ϕ_2 will be touched along a def-use edge from that split. Eventually, ϕ_2 will be split again to finally end up in its own partition.

Figure 4.8 Splitting with PHIs

Our splitting race here is crucial to our run time. We start at the three Leader Nodes, and work our way back into a partition of arbitrary size. The first time a side reaches a PHI, we move it in with that side. If the other side reaches the same PHI, we (only once per Node) convert it to a Leader. If only one side reaches the PHI, we leave it as a Follower. We do not need to know ahead of time which Follower PHI's (or how many) will go with which Leaders. The race alleviates us from having to maintain that information. The run-time analysis of the race is unchanged; we do no more work than twice the number of Nodes in the smaller split.

We give C++ code for a PHI Node's Follower-determination function below. A PHI remains a Follower if all live inputs come from the same partition. We return either a pointer to the PHI Node if it is not a Follower or some input Node in the same partition.

```
Node *PhiNode::Identity() {
    RegionNode *region := control;           // Handy access to the controlling REGION
    Node *n_part := NULL;                    // Some Node being Followed
    for( int i := 1; i < use_cnt; i++ ) {    // For all inputs do...
        // If the matching control (CFG path) is reachable do...
        if( (*region)[i]→type = Type_Reach ) {
            Node *in := (*this)[i];          // Handy access to the data input
            if( !n_part ) n_part := (*this)[i]; // First input partition found
            else if( n_part→part != in→part ) // Check that all inputs are congruent
                return this;                  // Incongruent inputs, NOT a Follower
        }
    }
    // Note: If n_part is NULL here, all input paths are dead, the PHI computes
    // Type_Top, is in the TOP partition and is not being split here!
    return n_part;                           // Congruent inputs, a Follower
}
```

We give C++ code for a MAX Node's approximation function below:

```

MaxNode::Compute() {
    const Type *t1 := in1→type;           // Quick access to input type
    const Type *t2 := in2→type;           // Quick access to input type
    if( t1 = Type_Top || t2 = Type_Top )   // If either input is undefined
        type := Type_Top;                 // ...then so is the result
    else if( t1→is_con() && t2→is_con() ) // If both inputs are constants
        type := Type(max(t1→con, t2→con)); // ...then compute the result
    else if( in1→part = in2→part )         // If the inputs are congruent
        type := t1;                       // ...then the result has same type
    else                                   // Otherwise, the result is not
        type := Type_Bottom;              // a compile-time constant
}

```

The PHI approximation function is similar, except that the primitive operation is lattice **meet** instead of maximum and we ignore dead input paths.

4.9.1 Losing Some Congruences

Unfortunately, our algorithm as presented loses some congruences amongst PHI Nodes. In Figure 4.8, ϕ_2 can go with either half. However, if there are more PHIs with the same shape as ϕ_2 they all need to go to the same side as ϕ_2 . The race selects sides arbitrarily. Thus two Nodes with ϕ_2 's shape can be split, despite their being congruent.

We can repair this at the expense of our asymptotic running time. After the race is over, we can move all the PHIs that are making the Follower \Rightarrow Leader transition into the larger partition. We also need to move everything that can be reached from such PHIs into the larger partition. In the worst case, this can be nearly everything in the smaller partition. When this happens we will have touched a large number of Nodes (up to half the partition), but the final size of the smaller partition might be a single Node. For a particularly bad sequence of partition splitting, this can cause Node visitations quadratic in the number of PHI Nodes.

Our implementation does not include this repair, does not recover these lost congruences, and remains $O(n \log n)$ asymptotically. A casual inspection of the optimized output did not reveal any obvious missed common subexpressions. In our test suite, we consistently found more common subexpressions than the classical techniques against which we compared. We do not believe these lost congruences occur very often in practice. While the repaired algorithm is not asymptotically as fast, we believe its actual running time will be essentially the same.

4.10 Using the Results

As my advisor is fond of saying, “*Knowledge does not make code run faster.*” We need to make use of the analysis. When the algorithm stops, we have a partitioning over our Nodes. All Nodes in a partition are congruent and compute the same value. The algorithm replaces such Nodes by a single representative (Leader) from the partition. Further, Nodes in the same partition compute the same Type and, if the Type is a constant, the representative Node can be a load-immediate of the constant. Finally we note that all unreachable code will be of type T.

We pre-order walk the program graph from the exit, following the use-def chains. For every visited Node, we make sure the corresponding partition has a representative ($O(N)$ time), creating one if necessary. We also make the representative Nodes’ use-def chains point to other representatives ($O(E)$ time). Then the graph formed by the representatives becomes our new program graph. We discard the old graph. We walk the representative’s use-def chains, so we do not walk the inputs to computations that compute constants (instead, we walk the inputs to the load-immediate Node, *i.e.*, none). Since we walked the final program graph’s use-def chains, the replacements contain no dead code; dead code is implicitly removed.

4.11 Summary

We have an $O(n \log n)$ algorithm for finding:

1. constants
2. unreachable code
3. global structural equivalencies
4. algebraic identities

It is optimistic, so it finds those algebraic identities that depend on structural equivalences that depend on constants that depend on algebraic identities. In particular, in Figure 3.11 we discover that the **print** statement always prints 1.

We implemented the algorithm and tested it on a large body of FORTRAN and C codes. In practice it is fast and runs in essentially linear time. A complete listing of run times and program improvements is in Chapter 5.

Chapter 5

Experimental Data

An unexamined idea, to paraphrase Socrates, is not worth having; and a society whose ideas are never explored for possible error may eventually find its foundations insecure.

— Mark van Doren (1894-1973)

5.1 Experimental Method

We converted a large test suite into a low-level intermediate language, ILOC [8, 6]. The ILOC produced by translation is very naive and is intended to be optimized. We then performed several machine-independent optimizations at the ILOC level. We ran the resulting ILOC on a simulator to collect execution cycle counts for the ILOC virtual machine. All applications ran to completion on the simulator and produced correct results.

The combined algorithm was implemented by the author. The classic optimization phases were implemented by members of the Massively Scalar Compiler Project at Rice.

5.2 Executing ILOC

ILOC is a virtual assembly language for a virtual machine. The current simulator defines a machine with an infinite register set and 1 cycle latencies for all operations, including LOADS, STORES and JUMPS. A single register can not be used for both integer and floating-point operations (conversion operators exist). While the simulator can execute an unlimited number of data-independent data operations in 1 cycle, we limited our output to 1 operation per cycle. ILOC is based on a load-store architecture; there are no memory operations other than LOAD and STORE. LOADS and STORES allow base+offset and base+index addressing. Adds and subtracts also have an immediate operand form. All

immediate operands are 32 bits long. ILOC includes the usual assortment of logical, arithmetic and floating-point operations.

The simulator is implemented by translating ILOC files into a simple form of C. The C code is then compiled on the target system using a standard C compiler, linked against either the FORTRAN or C libraries and executed as a native program. The executed code contains annotations that collect statistics on the number of times each ILOC routine is called, the dynamic number of each operation type executed and the dynamic cycle count. The statistics are printed to `stderr` as the program executes. We use UNIX redirection to capture the statistics in a separate file from the program output.

5.2.1 Quality of the simulation

The simulated ILOC clearly represents an unrealistic machine model. We argue that while the simulation is overly simplistic, it makes measuring the separate effects of optimizations possible. We are looking at machine-independent optimizations. Were we to include memory hierarchy effects, with long and variable latencies to memory and a fixed number of functional units, we would obscure the effects we are trying to measure.

A production compiler clearly must deal with these issues. Building a high quality back end is outside the scope of this thesis. We did not want the bad effects from a naive back end obscuring the effects we are trying to measure.

5.3 The Test Suite

The test suite consists of a dozen applications with a total of 52 procedures. The procedures and their static instruction sizes are given in Figure 5.1. All the applications are written in FORTRAN, except for **cplex**. **Cplex** is a large constraint solver written in C. **Doduc**, **tomcatv**, **matrix300** and **fpppp** are from the Spec89 benchmark suite. **Matrix300** performs various matrix multiplies. Since our machine model does not include a memory hierarchy (single cycle LOAD latencies), we are not interested in memory access patterns of the inner loops. Thus we choose **matrix300** over **matrix1000** for faster testing times, even cutting the matrix size down to 50. The remaining procedures come from the Forsythe, Malcom and Moler suite of routines. [20]

5.4 Comparing the Combined Algorithm

We compared the combined algorithm to a set of optimizations, run in reasonable combinations. In each case, we ran all codes through the optimizations and simulator, collecting statistics on the total number of operations executed. The optimizations are each implemented as a separate UNIX filter. The filters convert the ILOC code to text

form between each pass. We report both the raw cycle counts and speedups over unoptimized code. We performed the following optimizations:

clean: Clean removes empty basic blocks (branches to branches) and turns long chains of basic blocks into single large blocks.

coalesce: Many of the optimizations insert extraneous copy operations (*e.g.*, common subexpression elimination). Also, an easy algorithm for coming out of SSA form inserts a large number of extra copies. We coalesced them using techniques from graph coloring register allocators [5, 10].

combine: This phase combines logically adjacent instructions into more powerful instructions. This is commonly used to build addressing expressions for LOADs and STOREs. It also performs a variety of peephole optimizations, such as removing two **negates** in a row.

combo: The combined algorithm, as discussed in Chapter 4. This phase includes internally the effects of **dead** as part of the transformation step. **Combo** also includes a round of **combine**, **coalesce** and **clean** after the analysis.²⁰ The internal implementations are slightly different from the UNIX filters. We looked for places where the test suite used the differing idioms and changed one implementation or the other to match.²¹

cprop: Conditional constant propagation is an implementation of Wegman and Zadeck's algorithm [49]. It simultaneously removes unreachable code and replaces computations of constants with load-immediates of constants. It is *optimistic* in the sense that if a variable computing a constant allows a code section to be unreachable, and that because the code section is unreachable the variable computes a constant, **cprop** will discover this. After constant propagation, **cprop** runs a pass to fold algebraic identities that use constants, such as $x \times 1$ and $x + 0$, into simple copy operations.

²⁰ Normally we avoid such duplication of efforts. Unfortunately, we needed these passes to reasonably study **combo** before the separate Unix filter versions became available.

²¹ Differing implementations were a source of much confusion in getting comparable results. Compiler writers often extend published algorithms in minor ways, to find more common subexpressions or more constants. We were often faced with the choice of upgrading our implementation or upgrading the Unix filters (leading to a sort of compiler writer's one-up-manship).

dead: Dead code elimination removes code that cannot affect the output, even if executed. This algorithm starts at the program exit and walks the use-def chains to find all operations that define a value used by output operations or that affect the final result. Operations not visited in the walk do not affect the output and are removed. Our implementation is based on the work of Cytron, *et. al.* [15]

gval: Global value numbering implements Alpern, Wegman, and Zadeck’s global congruence finding algorithm [2]. Instead of using dominance information, *available expressions* (AVAIL) information is used to remove redundant computations. AVAIL is stronger than dominance, so more computations are removed [41].

parse: Usually used to test ILOC parsing, this pass includes a flag to split control-dependent basic blocks. This has the effect of creating basic blocks for loop landing pads and partially redundant expressions.

partial: Partial Redundancy Elimination is an implementation of Morel and Renvoise’s algorithm for removing partially redundant expressions, as modified by Drescher and Stadel [36, 18]. It also hoists code out of loops, if that code is not control dependent inside the loop. Since it is a global algorithm, it also performs local common subexpression elimination. Unfortunately, the algorithm has no understanding of algebraic identities and relies solely on lexical equivalence.

shape: This phase reassociates and redistributes integer expressions allowing other optimizations to find more loop invariant code [7]. This is important for addressing expressions inside loops, where the rapidly varying innermost index may cause portions of a complex address to be recomputed on each iteration. Reassociation can allow all the invariant parts to be hoisted, leaving behind only an expression of the form “base+index×stride” in the loop.

valnum: Valnum performs local value numbering with a hash table [13]. This method handles algebraic identities such as $x + 0$ or copy operations, commutativity, constant folding, and equal-functions-on-equal-inputs congruences, all within a single basic block.

Optimizations *not* performed include strength reduction, any sort of loop transformations (unrolling, interchange, peeling, loop unswitching), software pipelining, blocking for cache, scalar replacement, and register allocation. Scalar replacement and register allocation both change the address computations. They can speed up or slow down the simulated ILOC run-time. Strength reduction and loop unswitching both have strong effects on the amount of code executed in loops. The remaining optimizations have little effect on our simple virtual machine.

5.5 The Experiments

Combo, the combined algorithm, combines **cprop** (conditional constant propagation) with value numbering. If the global schedule is enforced (computations must remain in their original basic block) then the value numbering effects are equal to **valnum** (local value numbering) only. If the global schedule is ignored, the value numbering effects are similar to a combined **gval**, **partial**, and **valnum**. We tested both ways.

Combo always ends with a round of dead code elimination (as part of using the analysis results). We always followed any set of the classic optimizations with a round of **dead**.

Most of the phases use SSA form internally with a naive translation out of SSA at the end. Thus, most optimizations insert a large number of copies. We followed with a round of **coalesce** to remove the copies. This tends to empty some basic blocks (those blocks with only copies). We also used **parse** to split control-dependent blocks (**combo**, with the global schedule ignored, has the same effect), and some of those blocks go unused. We ran a round of **clean** to remove the empty blocks.

Combo and **shape** split complex ILOC instructions, such as LOAD from base+index into a simple ADD and a LOAD. This allows more common subexpressions to be found. However, a round of **combine** is required to reform the single LOAD instruction.

The global version of **combo** requires a round of global code motion to recover some serial order. This global code motion pushes operations down, to make them as control dependent as possible, without pushing them into loops. This heuristic both hoists loop

invariant code and, we hope, moves operations into less frequently executed paths. **Shape**, as part of exposing more common subexpressions, pushes operations down as far as possible (even into loops). **Partial** tends to reverse this, by hoisting code out of loops. However, **partial** is more conservative than **combo**, in that it will not hoist a control-dependent operation out of a loop (because that would lengthen a path that never takes a rare condition inside the loop). Thus both **combo** and the **shape/partial** pair perform some amount of global code motion.

Our experiments all follow this general strategy:

1. Convert from FORTRAN or C to naive ILOC.
2. Optionally run **shape**.
3. Run either **combo** or some combination of **parse**, **gval**, **partial**, **cprop** and **valnum**.
4. Clean up with **combine**, **dead**, **coalesce**, and **clean**.
5. Translate the ILOC to C with the simulator, then compile and link.
6. Run the compiled application, collecting statistics.

Variations on this strategy are outlined below in each experiment.

5.5.1 The “best code, reasonable compile times” strategy

We compared the global version of **combo** against **parse**, **gval**, **partial**, **cprop**, **combine**, **dead**, **coalesce**, and **clean**, as shown in Figure 5.2. This represents a strategy of compiling for the best possible code, with reasonable compile times. We expect **combo** to do well for two reasons: **combo**’s global code motion will move code into control-dependent regions, thus removing it from some execution paths, and **combo**’s analysis is better than repeating **gval**, **partial**, and **cprop** to a fixed point (see Chapter 3). We report in Figure 5.3 run times as a speedup over the unoptimized code.

Figure 5.2 Optimization strategy for “best code, reasonable compile times”

The total improvement over all applications is 2.2%. The average improvement per procedure is 4.7%. The average improvement is greater than the overall improvement because some long-running routines (such as **saxpy**) compiled to essentially identical code. This shows that both approaches do well with simple control flow and nested loops.²²

The routines **saturn** and **fmin** lose cycles compared to the phase-oriented approach because of **combo**'s global code motion heuristic. **Combo** hoists control-dependent code out of loops. In these cases, the controlling condition never comes true so the **combo** version ends up executing the code when the original program does not.

Figure 5.3 Best code, reasonable compile times

²² More precisely, we should say that this shows that both approaches do well with **saxpy**, a simple and heavily studied kernel.

Deblu and **pastem** do better for precisely the same reason. They both contain nested loops and complex control flow. The **partial** pass will not hoist the control-dependent code, while **combo**'s more aggressive global code motion will. These examples highlight the difference between PRE's safe and conservative approach and our code motion heuristic. Often our heuristic wins, but not always.

5.5.2 The “best code at any cost” strategy

We compared the global version of **combo** against **parse**, **gval**, **partial**, **cprop**, **combine**, **dead**, **coalesce**, and **clean** in Figure 5.4. The entire set of classic phases was then repeated. This represents a strategy of compiling for the best possible code, without regard to compile times. We report run times as a speedup over the unoptimized code in Figure 5.5.

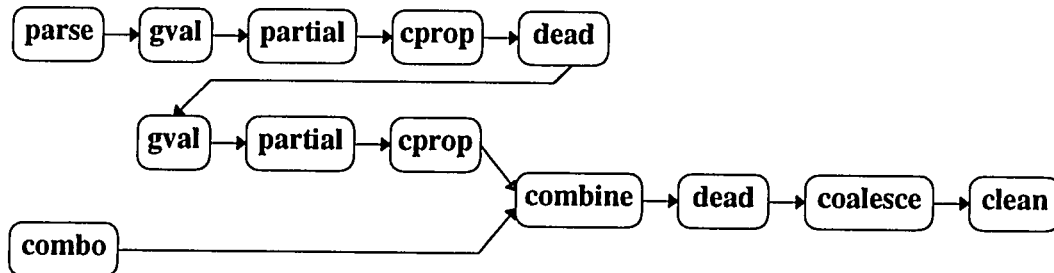

Figure 5.4 Optimization strategy for “best code at any cost”

The total improvement over all applications is 2.0%. The average improvement per procedure is 3.0%. As expected, the cycle counts for the repeated phases get closer, but do not reach, the cycle counts for the combined optimization. The average improvement per procedure is only 3.0% instead of 4.7%. Since repeating phases lowers the cycle count, the phase-ordering predicted by theory really occurs in practice.

Figure 5.5 Best code at any cost

5.5.3 The “Reassociate, then best code, reasonable compile times” strategy

We ran **shape** first, to reassociate all integer expressions. We then compared the global version of **combo** against **parse**, **gval**, **partial**, **cprop**, **combine**, **dead**, **coalesce**, and **clean** in Figure 5.6. This represents a strategy of compiling for the best possible code

Figure 5.6 Strategy for “Reassociate, then best code, reasonable compile times”

with reasonable compile times. We report run times as a speedup over the unoptimized code in Figure 5.7.

Running **shape** and **partial** together simulates the global code motion performed by **combo**. **Shape** does forward propagation of expressions, pushing computations into more control-dependent regions (in an attempt to get more grist for the value-numbering optimizations). **Partial** will hoist code out of loops as a side effect of suppressing partially redundant computations.

The total improvement over all applications is 2.2%. The average improvement per procedure is 7.8%. In general, reassociating improves all the speedups. However, the relative speedups (between **combo** and the phase-oriented approach) become more erratic.

Figure 5.7 Reassociate, then best code, reasonable compile times

5.5.4 The “Reassociate, then best code at any cost” strategy

We ran **shape** first, to reassociate all integer expressions. We then compared the global version of **combo** against **parse**, **gval**, **partial**, **cprop**, **combine**, **dead**, **coalesce**, and **clean**, as shown in Figure 5.8. The entire set of classic phases was repeated. This represents a strategy of compiling for the best possible code, without regard to compile times. We report run times as a speedup over the unoptimized code in Figure 5.9.

The total improvement over all applications is 1.7%. The average improvement per procedure is 4.4%. Again, **shape** improves the cycle counts on the whole. Repeating the classic optimization passes brings the cycle counts closer to what we get with **combo**.

Figure 5.8 Optimization strategy for “best code at any cost”

5.5.5 The “best simple” strategy

We compared the *local* version of **combo** against **parse**, **valnum**, **cprop**, **combine**, **dead**, **coalesce**, and **clean**. The local version of **combo** only finds common subexpressions within a single basic block, in addition to global constants and unreachable code. This represents a strategy of compiling using well known and simple to implement techniques. We report run times as a speedup over the unoptimized code in Figure 5.10. Note that no global code motion is done, in particular, loop invariant code is not hoisted.

The total improvement over all applications is 11.8%. The average improvement per procedure is 2.6%. We studied the differences, and determined that most of the differences were due to the inconsistent implementation of **valnum**. As an example, **valnum**

would not find two LOADs of the same address with no intervening STORE to be common subexpressions. There are numerous other missing identities, most of which are being corrected in a new version of **valnum**. Instead of a completely different implementation, **combo** relies on a simple command-line flag to switch between local and global value-numbering. Thus **combo** implements the same identities with the same code.

5.6 The Compile-Time Numbers

One of a compiler writer's concerns is *compile time*, the time it takes to compile code. Programmers doing development work will use a compiler many times a day and expect

the compiler to be fast. The pragmatic compiler writer must consider the running time of an optimization pass versus its expected gain on the compiled programs.

We measured the time to run the optimizations and perform the transformations of all the phases. We expect a real compiler implementation to keep a single intermediate representation between all passes; it would **not** convert to text between each pass. When we measured compile times we ignored time to parse the input, print the output, and pipe the text form from one process to the next. In the **combo** pass, our timings do not include the internal **clean**, **combine** and **coalesce** phases.

All timing runs are on an IBM RS/6000 Model 540, with 64M of memory. The test machine was lightly loaded (all other users logged off) and had no other running jobs. Each pass was timed running on each input file, with the output piped to `/dev/null`. We ran the pass on the input once to load disk pages and processor cache, then timed and averaged the next three runs. We measured wall-clock time.

Most of the classic passes have been carefully engineered to run fast, while still being written in a readable and maintainable style. Further speed improvements are certainly possible; often a single pass over the intermediate representation can serve for several analysis phases.

5.6.1 Combo timings

We looked at the time to run **combo** and correlated it with the static instruction count. In the “Parse, Combo” column of Figure 5.11, we show the times to run **combo** when we do parse-time optimizations, discussed in Chapter 7, beforehand. The parse-time optimizations are integrated pessimistic versions of the constant propagation, unreachable code elimination and global value numbering. Doing some optimization at parse-time reduces the size of the intermediate representation run against **combo**, which improves **combo**’s running time.

Figure 5.11 Optimization time vs. size

Optimization time vs size

We fit a power curve to the data with a good correlation coefficient. The equations indicate that our optimization times are slightly sub-linear. This is an excellent result. We can expect optimization time of large programs (*e.g.*, whole program analysis) to remain reasonable.

5.6.2 Combined algorithm vs. Classical approach

We compare the compile times between the **combo** algorithm and the sum of **gval**, **partial**, **cprop** and **dead**, as shown in Figure 5.12. We also look at repeating the classical passes one extra time. **Combo** is competitive with one pass each of **gval**, **partial**, **cprop** and **dead**, taking 1% less time across all files. **Combo** is faster by 51% when the classic phases are repeated. **Combo** is faster than the classic passes on the big files and slower on the small files, indicating that it has a higher startup cost but a lower running-time constant.

Figure 5.12 Optimization times

5.6.3 Combined algorithm vs. Classical approach, with parsing

We looked at the compile times between the **combo** algorithm using parse-time analysis and the sum of **gval**, **partial**, **cprop** and **dead**. With our Unix filter design, each pass had to reparse its input. We counted parse-times only once for all passes. **Combo** with parsing is faster than one pass each of **gval**, **partial**, **cprop** and **dead**, taking 42% less time across all files. Nearly all of this can be attributed to the parsing technology. ILOC is

a syntactically simple language, allowing **combo** to sport a simple hand-coded parser. The classic phases are using a lex/yacc coded parser.

Chapter 6

Optimizing Without the Global Schedule

When they began looking at the problem it rapidly became clear that it was not going to be easy to treat it optimally. At that point I proposed that they should produce a program for a 704 with an unlimited number of index registers, and that later sections would ...make index register assignments so as to minimize the transfers of items between the store and the index registers.

— John Backus on the separation of concerns in the Fortran I compiler, “History of Fortran I, II, and III”, History of Programming Languages Conference, 1978

We believe that optimizing compilers should treat the machine-independent optimizations (e.g., conditional constant propagation, global value numbering) and scheduling separately. We argue that modern microprocessors with superscalar or VLIW execution already require global code motion. Removing the schedule from the machine-independent optimizations allows stronger optimizations using simpler algorithms. Preserving a legal schedule is one of the prime sources of complexity in algorithms like PRE [36, 18] or global congruence finding [2, 41].

6.1 Removing the Control Dependence

Nodes in our intermediate representation have a control field. Section A.2.3 discusses viewing the control field as a use-def chain linking the Node to the basic block controlling the Node’s execution. This implementation of **control** dependence is identical to the other data dependences in the program: it is represented simply as a Node pointer. When we say control dependence, we mean a dependence on some controlling Node. This is **not**

the notion of control dependence discussed by Ferrante, Ottenstein and Warren in their paper “The Program Dependence Graph and Its Use in Optimization” [21].

We can remove the control dependence for any given Node simply by replacing the pointer value with the special value `NULL`. This operation only makes sense for Nodes that represent data computations. `PHI`, `IF`, `JUMP` and `STOP` Nodes all require the control input for semantic correctness. `REGION` Nodes require several control inputs (one per CFG input to the basic block they represent). Almost all other Nodes can live without a control dependence.²³ A data computation without a control dependence does not exactly reside in any particular basic block. Its correct behavior depends solely on the remaining data dependences. It, and the Nodes that depend on it or on which it depends, exists in a “sea” of Nodes, with little control structure.

The “sea” of Nodes is useful for optimization, but does not represent any traditional intermediate representation such as a CFG. We need a way to serialize the graph and get back the control dependences. We do this with a simple global code motion algorithm.

The job of the global code motion algorithm then is to build a CFG and populate the basic blocks with all the “free-floating” Nodes. It must preserve any existing control dependences (divides, subroutine calls and other possibly faulting operations keep their control dependences) and all data dependences. Beyond that, the scheduler has some flexibility. We use a simple heuristic: place code outside as many loops as possible, then on as few execution paths as possible.

6.2 Improving Optimizations

Removing the control dependences allows the combined optimization algorithm, *with no other changes*, to find global congruences. When the control dependences are intact, distinct control inputs from otherwise identical computations will force **combo** to treat the computations as being different. For example, in Figure 6.1 below the computation of $a + b$ is partially redundant. With the control dependences removed, the two `ADD` Nodes that implement the two expressions are identical (and congruent).

²³ The exceptions are Nodes which can cause exceptions: loads, stores, division, subroutine calls, etc. Stores also require the control input to handle the example shown in Section 6.4.

```

a := ...;
b := ...;
if( pred() ) {
    x := a + b;
    z := x + 0;
}
y := a + b;

```

Figure 6.1 Some code to optimize

Partial Redundancy Elimination (PRE) [36, 18] finds expressions that are redundant or partially redundant and replaces them with a single computation only when no execution paths are lengthened. The combined algorithm treats all congruent expressions as being redundant, removing all but one. The combined algorithm will remove every congruent expression that PRE removes. However, PRE will also remove redundant textually equivalent expressions that are not congruent. Also, the combined algorithm only solves half the problem PRE solves. The congruent expressions still have no control dependence, and require global code motion to place them correctly.

Global Value Numbering (GVN) [37] finds global congruences by using expression rank to hoist expressions as early as possible, then using a hash-based technique (bottom-up technique) to form partitions of congruent expressions. This hoisting allows GVN to find congruent expressions from different program paths. Again, the combined algorithm will find all these congruences because it uses a top-down congruence finding technique instead of a bottom up one, and because it also understands the algebraic identities used with hash-based techniques. In Figure 6.1, both GVN and the combined algorithm find z congruent to both x and y , while PRE does not.

6.3 Finding a New Global Schedule

The job of the global code motion algorithm is to build a CFG and populate the basic blocks with all the “free-floating” Nodes. It must preserve all existing control and data dependences. Beyond that, the scheduler has some flexibility. We use a simple heuristic: place code outside as many loops as possible, and then place it on as few execution paths as possible.

We use the following basic strategy:

1. Trace the control-carrying edges in the graph and build a CFG.
2. Find the CFG dominator tree.
3. Find loops and arrange them in a loop tree.
4. Schedule (select basic blocks for) all Nodes early, based on existing control and data dependences. We place Nodes in the first block where they are dominated by their inputs. This schedule has a **lot** of speculative code, with extremely long live ranges.
5. Schedule all Nodes late. We place Nodes at the last block where they dominate all their uses.
6. Between the early schedule and the late schedule we have a safe range to place computations. We choose the block that is in the shallowest loop nest possible, and then is as control dependent as possible.

We cover these points in more detail in the sections that follow. We will use the loop in Figure 6.2 as a running example. The code on the left is the original program. On the right is the resulting graph (possibly after optimization). As before, shadowed boxes are basic blocks, rounded boxes are Nodes, dark lines represent control flow edges, and thin lines represent data-flow (data dependency) edges.

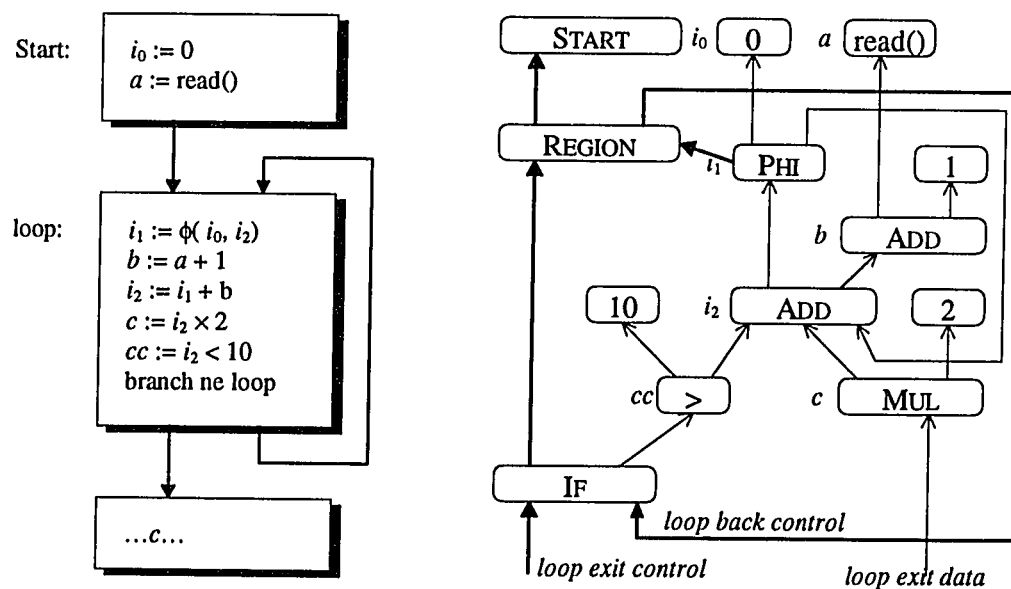

Figure 6.2 A loop, and the resulting graph to be scheduled

6.3.1 Finding the CFG

Because we did not build a *Program Dependence Graph* (PDG) [21], we can easily find the CFG in the optimized graph. IF, JUMP, and STOP Nodes all have a single control input. REGION Nodes have several, but all their inputs are control inputs. We walk the graph along the control edges, starting from the STOP Node. Each REGION Node starts a basic block, as does the START Node. Each IF, JUMP, or STOP Node ends a basic block. An IF Node starts two new basic blocks, a JUMP Node one. When we find two REGION Nodes in a row, we make a basic block for each and insert a JUMP Node between them. We keep a mapping between each REGION Node and the basic block it defines.

We do this by walking the control edges of the CFG. At each block end we find (or make) the RegionNode that marks the block's beginning. We then create the basic block. For each incoming control input to the RegionNode, we recursively make an incoming basic block and then make a corresponding incoming control edge in the CFG. We start by calling EndBlock() with the STOP Node:

```

EndBlock( Node *end ) {
    if( end->visit ) return;           // Find the block ended by Node end
    end->visit := TRUE;                // Already visited this basic block
    Node *start := end->control;        // Mark as visited
    if( start->Name != RegionNode::Name ) { // Find the control source for end
        RegionNode *r := new RegionNode; // If the block will not start with a Region
        r->in1 := start;                // Make a new RegionNode
        end->control := r;               // Its one input is the original control src
        start := r;                    // The block-ending Node use the new ctrl
    }                                  // Now we have a Region to start the blk

    Block *b := new Block( start, end ); // Make a basic block, using the Region
    start->block := b;                  // Record RegionNode's block in the Region
    int max := start->incnt();           // Input count to the RegionNode
    for( int i := 1; i < max; i++ ) {   // For all control inputs to the Region
        Node *c := (*start)[i];        // Get ith control input
        Node *d := (c->Name == ProjNode::Name) ? (*c)[1] : c; // Skip thru Projections
        if( d->Name == RegionNode::Name || // Back-to-back RegionNodes
            (d->Name == IfNode::Name && max > 2) ) { // or control-dependent block
            d := new JumpNode( c );     // New block ending
            Node *p := new ProjNode( d ); // Projection from the Jump
            (*start)[i] := p;           // Get control from the Jump's projection
        }
        EndBlock( d );                 // Recurse on the incoming block ender
        AddCFGEde( d->control->block, b ); // Add CFG edge from d's block to block b
    }
}

```

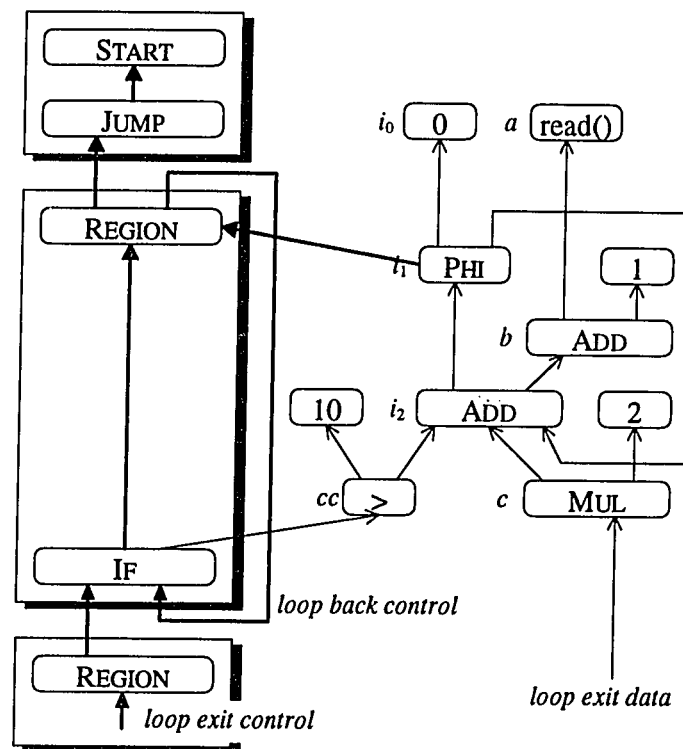

Figure 6.3 Our loop example, after finding the CFG

With the CFG in hand, we find the dominator tree by running Lengauer and Tarjan’s fast dominator finding algorithm [35]. We find loops using a slightly modified version of Tarjan’s “Testing flow graph reducibility” [44]. Chris Vick has an excellent write-up of the modifications and on building the loop tree [47]. We used his algorithm directly, and only mention the high points here.

1. The CFG is visited in a pre-order *Depth First Search* (DFS).
2. Any edge going from a high pre-order to a lower pre-order is a loop back-edge.
3. All blocks on a path from the loop exit to the loop header are in the loop.

4. Inner loops are joined into outer loops using *Union-Find* techniques [43].
5. Loops are formed into a *loop tree* as they are discovered. Nested loops are deep in the tree. The root represents the whole program. The first level down from the root are the outermost loops.
6. Irreducible loops are handled by allowing a set of loop header blocks (instead of a single loop header block) for each loop.

The dominator tree and loop tree give us a handle on expected execution times of basic blocks. We use this information in deciding where to place Nodes in the following sections. The running time of these algorithms is nearly linear in the size of the CFG. In practice, they can be computed quite quickly. We show the dominator and loop trees for our running example in Figure 6.4.

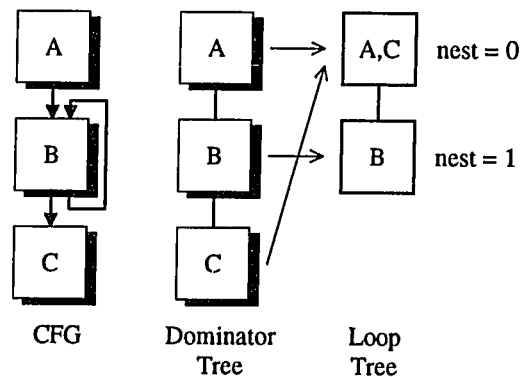

Figure 6.4 CFG, dominator tree, and loop tree for our example

6.3.3 Schedule early

Our first scheduling pass greedily places Nodes as early as possible. We place Nodes in the first block where they are dominated by their inputs. The only exception is Nodes that are “pinned” into a particular block because of control dependences. These include REGION Nodes (obviously; they map 1-to-1 with the basic blocks), PHI Nodes (these, too, are tightly tied to a particular block), IF, JUMP, and STOP Nodes (these end specific blocks), and any faulting instruction. This schedule has a **lot** of speculative code, with extremely long live ranges.

We make a post-order DFS over the *inputs*, starting at Nodes that already have a control dependence (“pinned” Nodes). After scheduling all inputs to a Node, we schedule

the Node itself. We place the Node in the same block as its deepest dominator-tree depth input. If all input definitions dominate the Node's uses, then this block is the earliest correct location for the Node.

The code that selects Nodes with control dependences and starts a DFS from them is straightforward; we only show the DFS code here. We use the control field both as a visit flag for the DFS and as the block indicator for a Node. We move a Node to a block by setting the control field.

```

void Schedule_Early( Node *n ) {
    int max := n→incnt();                // Get number of inputs to n
    for( int i := 1; i < max; i++ ) {    // For all inputs do...
        Node *in := (*n)[i];            // Get the ith input
        if( !in→control )                // If it has not been scheduled
            Schedule_Early(in);          // ...then schedule it
    }
    if( n→control ) return;              // Exit if we were a root
    Block *b := (*n)[1]→control→block;   // Get block of 1st input
    for( i := 2; i < max; i++ ) {        // For all remaining inputs
        Block *inb := (*n)[i]→control→block; // Get block of ith input
        if( b→dom_depth < inb→dom_depth ) // If ith input is deeper
            b := inb;                    // ...then select deepest input block
    }
    n→control := b→region;               // Set control dependence
}

```

One final problem: it is easy (and occurs in practice) to write a program where the inputs do not dominate all the uses. Figure 6.5 uses x in block 5 and defines it in block 4. The dominator building algorithm assumes all execution paths are possible; thus it may be possible to use x without ever defining it. When we find the block of the ADD Node in line 5, we discover the deepest input comes from the assignment to x in block 4 (the other input, sum_1 , comes from the PHI in block 3). Placing the ADD Node in block 4 is clearly wrong; block 4 does not dominate block 5.

```

1. int first := TRUE, x, sum0 := 0;
2. while( pred() ) {
3.   sum1 :=  $\phi$ ( sum0, sum2 );
3.2  if( first )
4.    { first := FALSE; x := ...; }
5.    sum2 := sum1 + x;
6. }

```

Figure 6.5 x 's definition does not dominate its use

Our solution is to leave in some “extra” PHI Nodes, inserted by the classic SSA translation [15]. We show the same code in Figure 6.6, but with the extra PHI Nodes visible. In essence, we treat the declaration of x_0 in line 1 as a binding²⁴ to the undefined type T. This value is then merged with other values assigned to x , requiring PHI Nodes for the merging. These PHI Nodes dominate the use of x in line 5.

```

1. int first := TRUE, x0 := T, sum0 := 0;
2. while( pred() ) {
3.   sum1 :=  $\phi$ ( sum0, sum2 );
3.1  x1 :=  $\phi$ ( x0, x3 );
3.2  if( first )
4.    { first := FALSE; x2 := ...; }
5.    x3 :=  $\phi$ ( x1, x2 );
5.1  sum2 := sum1 + x3;
6. }

```

Figure 6.6 Now x 's definitions dominate its uses

This problem can arise outside of loops as well. In Figure 6.7, the PHI Node on line 4 is critical. With the Phi Node removed, the computation of $f(x)$ on line 6 will be scheduled early, in the block on line 3. However, the block in line 3 does not dominate the block in line 6. In fact, there is no single block where the inputs to f dominate its uses, and thus no

²⁴ Since we are in SSA form every variable is assigned only once; we can treat assignment like binding.

legal schedule. The PHI Node tells us that it is all right; the programmer wrote code such that it appears that we can reach f without first computing its inputs.

```

1. int  $x_0 := T$ ;
2. if( sometime() )
3.    $x_1 := \dots$ ;
4.  $x_2 := \phi( x_0, x_1 )$ ;
5. if( sometime_later() )
6.    $y := \dots f(x_2) \dots$ ;

```

Figure 6.7 The PHI Node on line 4 is critical.

These PHI Nodes cannot be optimized away. They hold critical information on where the programmer has assured us that values will be available. In our framework, the optimization that would remove this PHI Node is the one where we make use of the following identity: $x = \phi(x, T)$. We ignore this identity.

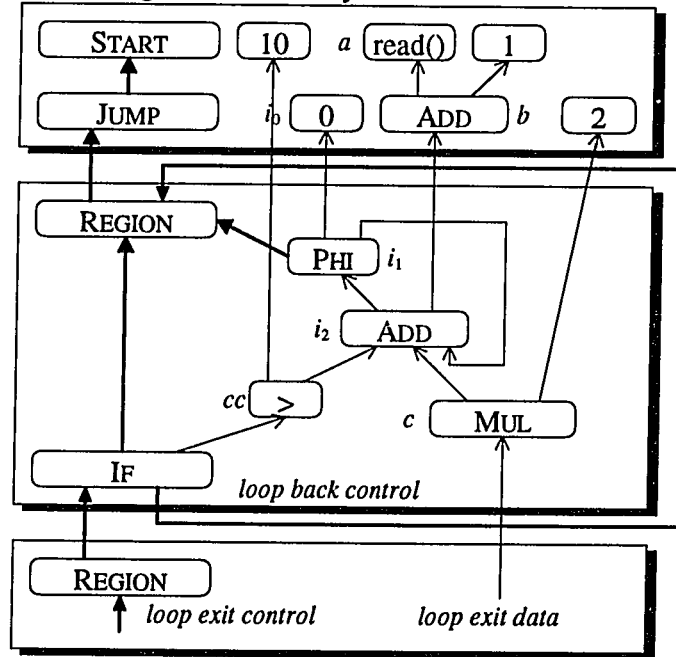

Figure 6.8 Our loop example, after scheduling early

In Figure 6.8 of our running example, scheduling early places the add “ $b := a + 1$ ” outside the loop, but it places the multiply “ $c := i_2 \times 2$ ” in the loop. The PHI Node is pinned into the block. The add “ $i_2 := i_1 + b$ ” uses the PHI, so it cannot be scheduled before the PHI. Similarly, the multiply and the compare use the add, so they cannot be placed before the loop. The constants are all hoisted to the start of the program.

6.3.4 Schedule late

We place Nodes at the lowest common ancestor (LCA) in the dominator tree of all uses. Finding the LCA could take $O(n)$ time for each Node, but in practice it is a small constant. We use a post-order DFS over *uses*, starting from the “pinned” Nodes. After visiting (and scheduling late) all of a Node’s children, we schedule the Node itself. Before scheduling, it is in the earliest legal block; the LCA of its uses represents the latest legal block. The earliest block dominates the latest block (guaranteed by the PHI Nodes we did not remove). There is a line in the dominator tree from the latest to the earliest block; this represents a safe range where we can place the Node. We can place the Node in any block on this line. We choose the lowest (most control dependent) position in the shallowest loop nest.

For most Nodes, uses occur in the same block as the Node itself. For PHI Nodes, however, the use occurs in the previous block of the corresponding control edge. In Figure 6.7 then, the use of x_0 occurs in the block on line 2 (not in block 4, where the ϕ is) and the use of x_1 occurs in the block on line 3.

As before, the code that selects Nodes with control dependences and starts a DFS from them is straightforward; we only show the DFS code here. Since the control field now holds useful information (earliest legal block for this Node) we require an explicit DFS visit flag.

```

void Schedule_Late( Node *n ) {
    if( n→visit ) return;           // Already visited? Skip
    n→visit := TRUE;                // Set visit flag
    int max := n→use_cnt();          // Get number of uses of n
    for( int i := 0; i < max; i++ ) { // For all uses do...
        Node *out := n→outputs[i];  // Get the ith use
        if( !out→pinned() )         // If it is not pinned
            Schedule_Late(in);       // ...then schedule it
    }
    if( n→pinned() ) return;        // Exit if we were a root
    Block *lca := NULL;              // Least common ancestor in dom tree
    for( i := 0; i < max; i++ ) {    // For all uses do...
        Node *out := n→outputs[i];  // Get the ith use
        Block *outb := out→control→block; // Get block of ith use
        if( out→Name = PhiNode::Name ) { // Use is a PhiNode?
            // This loop could be removed (and the code made asymptotically faster)
            // by using complex data structures. In practice it is never a bottleneck.
            for( int j := 1; j < out→incnt(); j++ )
                if( (*out)[j] = n ) // Find control path of use of n
                    // Find the block that the use is in
                    lca := Find_LCA( lca, (*out→control)[j]→control→block );
        } else
            lca := Find_LCA(lca, outb); // Find the LCA
    }
    //...use the LCA and current (early) control edge to pick a Node's final position
}

```

We use a simple linear search to find the least common ancestor in the dominator tree.

```

Block *Find_LCA( Block *a, Block *b ) { // Least Common Ancestor
    if( !a ) return b;                  // Trivial case
    while( a→dom_depth < b→dom_depth ) // While a is deeper than b
        a := a→immediate_dominator;    // ...go up the dominator tree
    while( b→dom_depth < a→dom_depth ) // While b is deeper than a
        b := b→immediate_dominator;    // ...go up the dominator tree
    while( a ≠ b ) {                    // While not equal
        a := a→immediate_dominator;    // ...go up the dominator tree
        b := b→immediate_dominator;    // ...go up the dominator tree
    }
    return a;                           // Return the LCA
}

```

6.3.5 Selecting a Block

We may have to choose among many blocks in the safe range for a Node. The heuristic we use is to pick the lowest (most control dependent) position in the shallowest loop nest. This primarily moves computations out of loops. A secondary concern is to move code off of frequently executed paths into if statements.

When we select a Node's final position, we affect other Nodes' latest legal position. In Figure 6.9, when the Node " $b := a + 1$ " is scheduled before the loop, the latest legal position for "1" is also before the loop. To handle this interaction, we select Nodes' final positions while we find the latest legal position. Here is the code to select a Node's final position:

```

...find LCA, the latest legal position for this Node. We already have the early block.
Block *best := lca;           // The best place for n
while( lca ≠ n→control ) {    // While not at earliest block do ...
    if( lca→loop→nest < best→loop→nest ) // Shallower loop nest?
        best := lca;           // Save deepest block at shallower nest
    lca := lca→immediate_dominator; // Walk up the dominator tree
}
n→control := best→region;     // Set control dependence
}

```

The final schedule for our running example is in Figure 6.9. The MUL Node's only use was after the loop. Late scheduling starts at the LCA of all uses (the last block in the program), and searches up the dominator tree for a shallower loop nest. In this case, the last

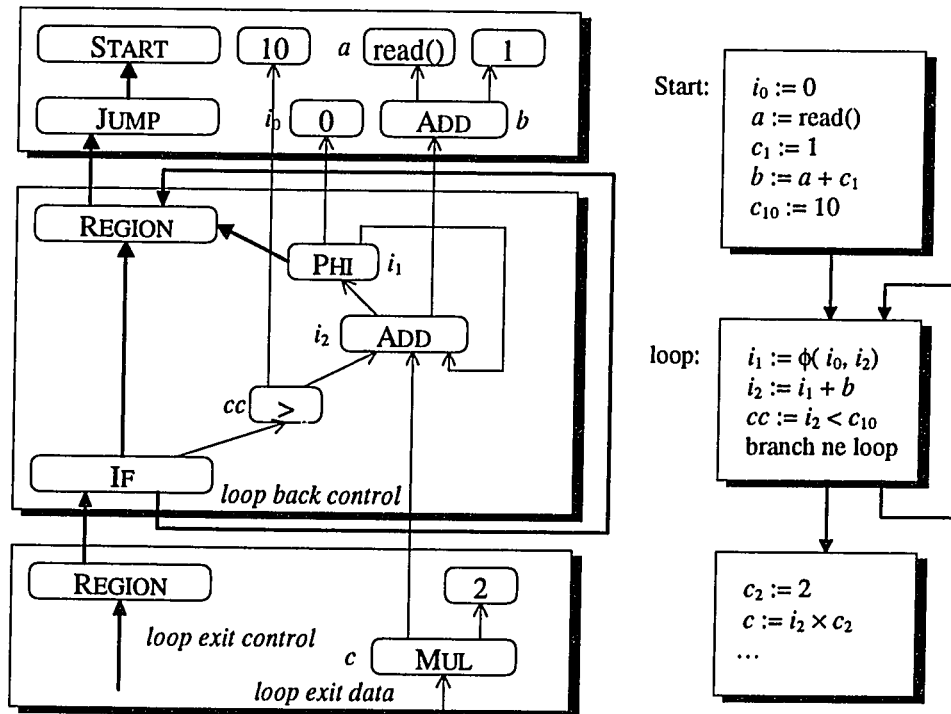

Figure 6.9 Our loop example, after scheduling late

block is at nesting level 0 and is chosen over the original block (nesting level 1). After the multiply is placed after the loop, the only use of the constant 2 is also after the loop, so it is scheduled there as well. The compare is used by the IF Node, so it cannot be scheduled after the loop. Similarly the add is used by both the compare and the PHI Node.

6.4 Scheduling Strategies

The time to run the scheduler varied between 1/15th and 1/24th of the time it took to parse the code. Even on the largest files, scheduling time was a small fraction of a second. Given the relatively low cost of this scheduler, we believe it is worthwhile to explore global code motion further. An in-depth study is outside the scope of this research, but we present an idea here.

One of the problems with this scheduler is that it will hoist a common expression to cover all uses, even if this lengthens some paths. For some of our test cases, this was the major cause of lost performance. A more clever scheduler could *split* Nodes, then schedule them so that no computation occurred on any path unless it was eventually used (*i.e.*, place computations where they are very busy). In the CFG of Figure 6.10, the combined algorithm removes two redundant copies of “ $a + b$ ”. This forces the scheduler to cover all uses, lengthening the enclosed path.

Figure 6.10 A path is lengthened.

By splitting the computation the scheduler increases the total code size, but shortens one path length. A better schedule is shown in Figure 6.11.

Figure 6.11 Splitting “ $a + b$ ” allows a better schedule.

For loop-free code the splitting scheduler makes no *partially dead code*. Partially dead code is dead on some paths and not others. Splitting expressions allows the scheduler to cover all uses without lengthening any path. *Partial Dead Code Elimination* (PDCE) [34] shortens execution time by moving expressions that are dead on some paths and not others to those paths in which the expression is used. For loop-free code, a splitting scheduler will place partially dead expressions only on the paths that use them. The effect is similar to PDCE; the new global schedule has no partially dead expressions.

With loops, our scheduler can create partially dead code. Loop-invariant conditional expressions are hoisted before the loop, under the assumption that they will be used many times. As long as they are used at least once, this heuristic is not worse than leaving the code in the loop, and it can be much better. We could make a more informed choice if we had more information on the loop bounds or the frequency with which the conditional is taken.

Chapter 7

Parse-time Optimizations

7.1 Introduction

With a minor change to the parser, we can do optimization *while parsing*. Parse-time optimizations remove simple constant computations and common subexpressions early on, before the slower global optimizations. This reduces the peak memory required by the optimizer and speeds the global optimizations that follow.

Parse-time optimizations must be pessimistic (as opposed to optimistic), because we do not know what the not-yet-parsed program will do. They do not find as many constants or common subexpressions as the global techniques, particularly around loops. For this reason they are not a replacement for optimistic transformations.

Our pessimistic analysis requires only use-def information, which we can gather as we parse the code. The compiler looks at (and changes) a fixed-size region of the intermediate representation. Code outside the region is not affected by the transformation; code inside the region is transformed without knowledge of what is outside the region. Thus our pessimistic analysis is also a local, or peephole, analysis. Optimistic transformations require def-use information, generally not available during parsing, and global analysis (see Section 2.3).

7.2 The Parser Design

The parser needs to build use-def information incrementally, because the peephole optimizations require it. Use-def information, in turn, relies on SSA form. So we want our parser to build SSA form incrementally. We begin with building use-def information on the fly.

7.2.1 Incremental Use-Def Chain Building

The actual parsing and syntax checking are not interesting here. For this exposition, our input is ILOC, the virtual machine language described in Chapter 5. However, any parser can use the techniques described. Use-def building only becomes involved after the parser has discovered a simple expression, such as $a := b + c$. The parser needs to create an ADD Node for the expression, then fill in the input fields (b and c) and make the result accessible by way of a somehow.

The parser maintains a map from names to the Nodes that compute values. This map is often called a *symbol table*. When a name occurs in an expression, the parser uses the map to find the definition for that name. When a name is defined in an expression, the parser replaces the previous definition with the new definition. When a name goes out of scope (because some lexical entity, such as a function body, ends), the name is removed from the mapping. The exact design of this mapping will vary, depending on the language being parsed and the parser designer. For our purposes, we assume we can convert a name to Node in constant time. In our implementation, we map names to unique integer indices. We then index into a simple array of pointers to Nodes.

Figure 7.1 Building use-def chains for the expression $a := b + c$

In Figure 7.1, we show our parser building an ADD Node and updating the mapping for name a . The mappings are shown with dashed lines. First the parser builds the ADD Node, using the tools outlined in Appendix A. Next, the parser maps the names b and c to Nodes. Pointers to these Nodes are inserted in the ADD Node, effectively creating use-def chains. Finally, the mapping is altered to make a map to the ADD Node, destroying any previous mapping for a .

This sequence resembles classic value-numbering over a basic block and works well for straight-line code [1]. The amount of work to do per expression parsed is minimal: two symbol table lookups (hash table lookups), one Node creation (test and bump the Arena pointer, initialize internal fields), two stores of use-def chain pointers in the Node, and one symbol table alteration (hash table lookup). When we have to handle control flow, however, this approach shows some weakness.

7.2.2 Control Flow and Incremental ϕ -Function Insertion

Although *Static Single Assignment* is often associated with the methods that create it or the number of ϕ -functions inserted, it is a property of programs. We use a method that does not result in *minimal* or *pruned* SSA form. Our method inserts asymptotically more ϕ -functions than the published SSA building algorithms. In practice, our technique is fast and efficient. What is more important, the method is incremental so we can use the SSA form while parsing.

When we reach a point where control flow splits (a conditional branch), we make a copy of the current mapping in effect. We use the separate copies when parsing down the different control flow paths. At points where control flow merges, we need to insert a ϕ -function for every name that merges different values. We show a simple example in Figure 7.2. We clone the mapping at the conditional expression. Along the left-hand path we use and update the mapping when we build the ADD Node. At the merge point we

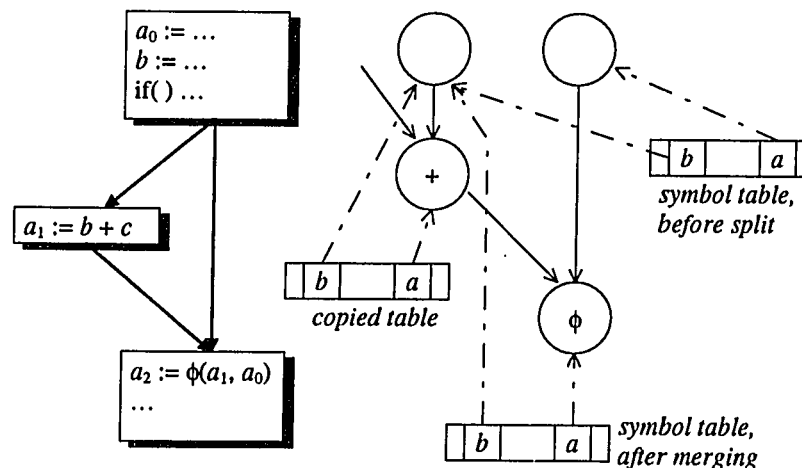

Figure 7.2 Incrementally building SSA in the presence of control flow

compare the original and the copied maps. b 's value remains the same in both; no ϕ is required. We changed the mapping for a , so we must insert a PHI Node. After merging we delete the copied map and continue with the (now updated) original map.

7.2.3 Labels and Loops

At loop entry points, and at labels we may need to merge mappings without having seen all the control flow paths leading to the merge point. A very conservative solution would be to assume all values are changed and insert a ϕ -function for every value. However, values may be defined in a loop and carried around by an as-yet-unparsed control flow edge. Such values would not be in our conservative merge, since they were not in the original mapping.

Instead, we keep a copy of the current name to value mapping at the loop head or label, as in Figure 7.3. As control flow paths that lead to the label are parsed, we merge the associated mappings. For the fall-through path below the label we make an empty mapping. If we reference some name that is not in the (new, empty) mapping, we need to come up with a value. We assume the value will be modified by the unparsed control flow edges, insert a ϕ -function at the loop head's mapping, and also insert the same ϕ -function mapping in the current map, as in Figure 7.4. Later references to the same name will map to the same ϕ -function, as in Figure 7.5.

Figure 7.3 Incrementally building SSA; before the label

Figure 7.4 Incrementally building SSA; after referencing b

Figure 7.5 Incrementally building SSA; after defining b

Our conservative approach requires us to insert many extra ϕ -functions beyond what *minimal* SSA form would insert. For loops, peephole optimization immediately removes most of the extras. For labels, the ϕ -functions cannot be peephole optimized until the label can no longer be reached. The remaining extra ϕ -functions are removed during the course of global optimization.

The simplicity of our approach allows us to write tight, fast code. Our constant of proportionality is very low. In practice, this technique is competitive with the asymptotically better approaches. It also allows the peephole optimizer to use SSA form incrementally.

7.3 The Peephole Optimizer

A simple peephole optimizer does all our parse-time optimizations. The power of this approach depends heavily on having use-def chains. The peephole optimizer looks at a fixed size instruction “window”, but the window looks over logically adjacent instructions,

not sequential instructions. Thus we can optimize the current instruction with instructions far away in the program text.

Another way we strengthen our optimizer is by dropping the global schedule, discussed in Chapter 6. This allows us to perform optimizations across basic block boundaries, an unusual feature for a peephole optimizer.

7.3.1 The Parser-Optimizer Interface

We want to interleave parsing and optimization with a minimum of fuss. To do this, we need to design our parser with optimization in mind. In addition, we need to supply the optimizer with enough information for it to get the job done. The optimizer needs use-def information and the existing program graph and nothing more. The optimizer, on the other hand, cannot modify the program wholesale. The parser needs to maintain mappings between the names being parsed and the program being produced.

The interface between the parser and the optimizer is just a single function call: Peephole. After the parser has parsed an expression and built a Node, but before it maps the new Node to a name, it calls Peephole. Peephole attempts to replace the recently built Node with an existing one or a simpler one. Peephole returns a replacement Node for the parser, returning the original one if it cannot optimize.

Figure 7.6 Incrementally building SSA in the presence of control flow

In Figure 7.6, the expression “ $a := b + c$ ” has been parsed and inserted in the program graph. The parser then

1. parses the common expression “ $d := b + c$ ”,
2. builds an ADD Node with the appropriate inputs,

3. calls Peephole on the ADD Node, and
4. creates a mapping from the name d to the Node returned by Peephole.

7.3.2 Peephole

We give the code for Peephole in Figure 7.7. Peephole relies heavily on virtual functions to compute constants, to find identities and to use the hash table.

There are many possible optimizations; we give code for only these few:

Removing copies: We use the original value instead of the copy, making the copy instruction dead.

Adding two constants: Anytime the inputs to a primitive are all constants, the primitive can be evaluated at compile time to yield a constant result.

Adding a zero: Several primitives have an identity element that converts the primitive into a copy.

Value-numbering: This finds instances of the same expression and replaces them with copies. The method used is a hash-table lookup where the key is computed from the inputs and the opcode. Because we have removed the control edge, we will find common subexpressions globally. We then require the global code motion

```

Node *Peephole( Node *n ) {
    Node *tmp;
    n→Compute();
    if( n→type→constant() )
        tmp := new ConNode( n→type→get_constant() );
    else {
        tmp := n→Identity();
        if( tmp = n ) {
            tmp := hash_table_lookup( n );
            if( !tmp ) {
                hash_table_insert( n );
                return n;
            }
        }
    }
    delete n;
    return tmp;
}

```

Figure 7.7 Peephole optimization

pass to generate correct code.

Subtracting equal inputs: Subtracting (comparing) the results of the same instruction is always zero (equal). Similarly, merging equal inputs in ϕ -functions always yields that input.

In practice, we find that array addressing expressions are a rich source of common subexpressions. Because FORTRAN allows a generic lower array bound, we commonly find code that subtracts a lower bound of zero from an index before scaling. All these optimizations interact, so that finding one can lead to finding more.

7.3.3 Control-Based Optimizations

Having control as an explicit edge means we can use control in our optimizations. REGION Nodes with only 1 control input are an identity on that input. This allows Peephole to fold up a long string of basic blocks into one large one. An IF instruction with a constant test produces control out of only one of two edges. The “live” control edge is an identity function of the IF’s input control. For the “dead” control edge, we use the special type Top. REGION and PHI Nodes ignore the Top input and merge control and data from only the live paths.

7.4 Experimental Data

We ran the optimizer with and without the global optimizations, to compare the quality of just the peephole optimizer (and global code motion algorithm) against a stronger global analysis. Our test suite and experimental method are the same as in Chapter 5.

We also measured optimization time with and without the peephole pass. Across all applications, peephole optimization followed by global analysis took 108.8 seconds. Global analysis alone took 116.1 seconds. Using the peephole pass saved 6.3% on total compile times.

7.4.1 Peephole vs. global optimizations

We ran the peephole optimizer and compared it to the **combo** pass. The total improvement was -1.9%, and the average improvement was -0.8%. As the numbers in Figure 7.8 show, the peephole optimizer does very well. Global analysis gets only a few

percentage points more improvement. Rather surprisingly, this means that most constants and common subexpressions are easy to find.

7.5 Summary

We found that most constants and common subexpressions are easy to find; they can be found using a simple peephole analysis technique. This peephole analysis was done at parse-time, lowering total compilation time by over 6%. To do strong peephole analysis at parse-time requires SSA form and use-def chains. We implemented a parser that builds SSA form and use-def chains incrementally, while parsing.

Chapter 8

Summary and Future Directions

8.1 Future Directions

The combined algorithm is powerful, but not so powerful that it can not be extended again. Currently, the constant propagation lattice supports floating-point and double precision constants, integer ranges with a stride and code address (label) constants (useful for tracking indirect jumps and function calls). We could enhance the lattice to support propagation of pointer constants, as a first step in doing pointer analysis. We could also enhance the congruence finding portion, by using dominance information or by allowing Nodes to be congruent within an affine function.

8.1.1 Improving Memory Analysis

Right now the memory analysis is very weak: the analysis lumps all arrays and variables into one simple state. We could clearly generate a more precise (and larger) program graph by breaking this state up into pieces. We would generate one STORE for each chunk of memory not dynamically allocated. These would all be produced by the START Node, and sliced out by the appropriate PROJECTION. LOADs and STOREs to specific STOREs would have a dependence to the right PROJECTION. The analysis can handle aliasing by forcing many STOREs to mingle in a UNION Node. LOADs from the UNION would be affected by any STORE to the component parts, but not by unrelated STOREs. After a STORE to a UNION (perhaps required because of an aliased address), the combined STOREs would again be split apart to allow more precise analysis to follow.

8.1.2 Incremental Dominators and the PDG

Currently, our REGION Nodes connect to one another in the style of a CFG. The control edges correspond closely with the edges in a CFG, so that constructing a CFG from the program graph is a simple exercise. A more powerful representation is an operator-

level PDG [21]. Here, control edges denote *control dependence*, a stronger notion than the edges in a CFG. We could use PDG-like control edges instead of CFG-like control edges to find more constants and congruences.

```

if( x ) then a := 1;
else a := 2;
if( x ) then b := 1;
else b := 2;

```

Here a and b clearly compute the same value. However, using the CFG notion of control edges our intermediate representation will not discover this. Basically, the name a is mapped to a ϕ -function merging 1 and 2, depending on a test of x in the first IF Node. The name b is equivalent, except that the ϕ -function depends on the second IF Node. The two IF Nodes are not equivalent; the first IF takes control from above and the second IF takes control from the merge point below the first IF.

Control dependence would allow the merged control below the first IF to be equivalent to the control above the first IF. The two IF Nodes would take in congruent inputs (same control, same test of x) and have equivalent opcodes. Analysis would find that they are congruent. Likewise the two ϕ -functions will then be found congruent.

Building a PDG requires dominator information. To build the PDG in a combined algorithm would require some type of incremental dominator algorithm. Control edges are dead until proven reachable in the combined algorithm. As the algorithm finds control flow-like edges to be reachable, the edges are (in essence) inserted into the CFG. The CFG's dominator tree would then need updating, possibly breaking some congruences based on dominator information.

The advantage of building a PDG is the discovery of more congruences. The disadvantage is that serialization is more difficult. Some recent work has been done on serializing an operator-level PDG, but not in time for this work [40].

8.1.3 Loops and Induction Variables

One of the more powerful optimizations relies on discovering periodicity in the program. Induction variable elimination and strength reduction take advantage of regular recurring patterns of computation. Our optimizations work on a Node (conditional constant

propagation) or between two Nodes (congruence finding) but not on whole loops. We would like to discover a way to fold entire loops into our analysis.

Currently, the congruence finding algorithm works around loops and will find congruences between equivalent induction variables. However, it will not discover induction variables related by an affine function. We could enhance our congruence finding by allowing two Nodes to be *affine-congruent* if they are congruent within an affine function. In each partition we would choose a *base* Node. Other Nodes would be related to the *base* Node by an affine function kept for each Node during analysis.

Under the old congruences, two Nodes compute the same value if they are in the same partition. In different partitions we cannot make any claim about whether they never have the same value. If two Nodes are *affine-congruent*, then we can state whether they definitely compute the same value (same scale and offset) or never compute the same value (same scale and different offset) or we can make no claim (different scale and offset). With this analysis the combined algorithm would find congruences between induction variables related by an affine function.

8.1.4 Commutativity

Two expressions " $a + b$ " and " $b + a$ " should be congruent. Our current combined algorithm does not find them congruent, because the inputs to addition are treated as being ordered. We partially alleviate this by placing all inputs in some canonical order during our parse-time optimizations. However, sorting the inputs does not handle the more general problem of discovering " $a + b$ " and " $d + c$ " to be congruent knowing that a and c are congruent, as are b and d . Ordering the inputs requires that we know the a, c and b, d congruences before we look for the $(a + b), (d + c)$ congruence. We can construct an example where the congruences are linked; to discover one requires discovering the other and *vice-versa*. To avoid this phase-ordering problem we need to extend the combined algorithm to discover these congruences optimistically.

8.2 Summary

We defined what it means to use the *optimistic assumption*: discover the facts in our analysis in a top-down, instead of a bottom-up, fashion. Assume the best; all expressions are undefined (instead of constant or unknown), all code is unreachable, and all expressions are congruent. Then prove what is actually a constant, reachable or not congruent. Similar to an inductive proof, you get to use the facts you assumed until proven otherwise. In the presence of cycles in the analysed dependences, using the optimistic assumption can allow you to find more facts.

We used the optimistic assumption in defining a very general framework for combining optimizations. We showed a simple method to finding the optimistic solution to an analysis in the framework. We showed how to mix, or combine, analyses, and under what conditions the combined analysis would remain solvable and profitable. We then combined *Conditional Constant Propagation* and *Value Numbering*. Because *Value Numbering* introduces an $O(n^2)$ number of equations, our solution time was also $O(n^2)$.

We then introduced a more complex algorithm that finds the solution to the combined *Conditional Constant Propagation* and *Value Numbering* in $O(n \log n)$ time. The combined algorithm is based on Hopcroft's DFA minimization algorithm, then extended by Alpern, Wegman and Zadeck to find congruences in program graphs. We extended the algorithm again to propagate constants while finding congruences. We then introduced other forms of congruences: those caused by constants and algebraic identities.

We ran a series of experiments to determine (1) if the combined algorithm improved program run times over compiling with a series of separate phases and (2) if the combined algorithm ran fast enough to be competitive. We discovered that the combined algorithm improved some codes by as much as 30%, while almost never slowing down any code. The combined algorithm was competitive in compile times as well, running about 1% faster than a single pass of the separate pieces when counting optimization time alone. If more separate optimization passes are desired (to get improved running times) the combined algorithm becomes significantly faster. When we counted both parse-times and compile-times, the combined algorithm was also significantly faster.

By dropping the control edges from data computing Nodes, we allowed the combined algorithm to discover global congruences. However, Nodes without control edges exist in a “sea of Nodes”, with no obvious serial order. To serialize the program graph, we must find a global schedule. We presented an algorithm for globally scheduling the program graph. We first discover the CFG, dominators and loops. We then schedule early, hoisting code out of loops but making much speculative code and long live ranges. We then schedule late, making code more control dependent as long as it does not go into any loop. This scheduling is extremely fast and often hoists more code out of loops than *Partial Redundancy Elimination*.

Because our intermediate representation has explicit use-def chains, we can perform strong peephole optimizations on it. Peephole optimizations are a form of pessimistic analysis and cannot find as many constants and congruences as analyses using the optimistic assumption. Nonetheless, our peephole optimization finds most constants and congruences. Since we can find use-def chains while we parse, we perform peephole optimizations while parsing. This speeds total compile time (parsing plus global optimization) by 6% and lowers peak memory. To find use-def chains while we parse, we presented a method of building SSA form incrementally.

Finally we looked at a number of ways to improve the analysis. We can extend the memory analysis to handle statically declared arrays and variables. We can use *control dependences* as in the PDG. We can allow expressions to be congruent modulo an affine function, allowing the combined algorithm to find induction variables.

We have shown that analyses can be combined, and that they can be profitably combined. We have shown an $O(n \log n)$ algorithm for combining *Conditional Constant Propagation* and *Global Value Numbering*. We ran experiments to prove that this combination runs fast in practice and improves program runtimes.

Appendix A

Engineering

A designer knows he has achieved perfection not when there is nothing left to add, but when there is nothing left to take away.
— Antoine de Saint-Exup'ery (1900 -1944)[†]

A.1 Introduction

Intermediate representations do not exist in a vacuum. They are the stepping stone from what the programmer wrote to what the machine understands. Intermediate representations must bridge a large semantic gap (for example, from FORTRAN 90 vector operations to a 3-address add in some machine code). During the translation from a high-level language to machine code, an optimizing compiler repeatedly analyzes and transforms the intermediate representation. As compiler *users* we want these analyses and transformations to be fast and correct. As compiler *writers* we want optimizations to be simple to write, easy to understand, and easy to change. Our goal is a representation that is simple and lightweight while allowing easy expression of fast optimizations.

This chapter discusses the intermediate representation used in the compiler that implements the analyses discussed in earlier chapters. The intermediate representation is a graph-based, object-oriented structure, similar to an operator-level *Program Dependence Graph* or *Gated Single Assignment* form [4, 21, 26, 38]. The final form contains all the information required to execute the program. What is more important, the graph form explicitly contains use-def information. Analyses can use this information directly without having to calculate it. Transformations modify the use-def information directly without requiring separate steps to modify the intermediate representation and the use-def infor-

[†] The French author, best known for his classic children's book "The Little Prince", was also an aircraft designer.

mation. The graph form is a simple single-tiered structure instead of a two tiered *Control-Flow Graph* containing basic blocks (tier 1) of instructions (tier 2). This single tier simplifies the design and implementation of the combined algorithm.

A.1.1 Optimizations in the Front End

One of the reasons for having the intermediate representation contain use-def information is that we can perform low-level pessimistic optimizations while we are parsing the high-level input. These low-level optimizations (such as value numbering and constant propagation) reduce the intermediate representation size, speeding later global optimistic analyses. As we show in Chapter 7, these parse-time transformations by themselves do almost as well as the global versions, but with significantly less compile-time cost.

Our pessimistic analysis requires use-def information and SSA form. We gather use-def information and incrementally build SSA form as we parse the code. The compiler looks at (and changes) a fixed-size region of the intermediate representation. The transformation does not effect code outside the region. The analysis transforms code inside the region without knowledge of what is outside the region.

A.1.2 Overview

In Section A.2, we introduce objects that make up our intermediate representation. In Section A.3, we use C++'s inheritance to give more structure to our instructions and to speed up their creation and deletion. In Section A.4, we drop the CFG altogether, replacing it with instructions that deal with control. In Section A.5, we discuss how we handle a variety of problematic instruction features, including subroutines, memory, and I/O. In Section A.6 we look at related work, contrasting our intermediate representation with other published representations. The rest of this chapter will demonstrate the intermediate representation using concrete C++ code and the design decisions that lead us here.

A.2 Object-Oriented Intermediate Representation Design

The intermediate representation uses a simple 3-address, load/store, infinite register virtual machine to represent programs. Internally we represent a virtual machine instruc-

tion as an instance of a C++ class inheriting from the Node class. Each different kind of instruction will use a different class derived from Node.

Instances of class Node contain almost no data; instruction-specific information is in classes that inherit from Node. We show a slice of the Node class hierarchy in Figure A.1. Node1, Node2, Node3, and NodeX define 1-input, 2-input, 3-input and many-input Nodes respectively. AddNodes define instances of algebraic rings, including the additive identity, commutativity, and associativity. The IntAddNode class merely provides the additive identity element (integer 0) and a unique string name used in printing (“iADD”), and inherits all other behaviors.²⁵ Finally, a 3-address integer add (“iADD r17 r99 => r101”) is an instance of class IntAddNode.

Figure A.1 Part of the class Node hierarchy

A.2.1 Node class Concrete Implementation

Class Node, shown in Figure A.2, holds only the virtual function pointer and basic block pointer for the object. We represent basic blocks as another kind of Node, described in Section A.4. In Chapter 6, we show that often we can do without the control field for our semantics and optimizations. Only during the final scheduling phases do we need to know in what basic block an instruction resides. Notice that the Node object does not contain an **opcode** field of any sort. The virtual function pointer is unique to each class; we will use it as the instruction’s opcode. If we need to perform an opcode-specific function, we will use a virtual function call.

²⁵ FloatAddNode uses a compile-time switch to determine if floating-point arithmetic is associative and distributive.

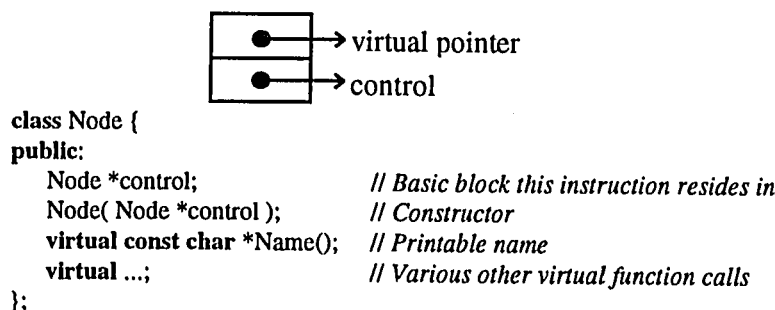

Figure A.2 Object layout and code for class Node

A.2.2 Single Pointer Use-def Edges

Instructions in a typical intermediate representation contain a list of virtual machine registers that the instruction reads or modifies. To find the instructions that produce the value being used in this instruction requires use-def information. Use-def information is useful for many optimizations. Storing it in our Nodes along with the used machine registers is somewhat redundant. Just the register number is nearly enough information to build use-def chains. However, many instructions modify machine registers; no single defining instruction may exist. To correct this problem we put our program in static single assignment form. SSA form requires ϕ -functions, which are treated like other Nodes.

With every use being defined by a single instruction, our use-def chains can just be a pointer to the concrete representation of the defining instruction. With use-def information we no longer need machine registers, so we will not include them. Class Node2, shown in Figure A.3, is the class of 2-input, 1-result instructions. It inherits the virtual function pointer and basic block pointer from Node and adds 2 use-def pointers. Node2 also defines virtual functions for accessing these pointers.

Note that our use-def edges consist of just the single pointer. We do not require more complex edge structures, such as linked lists. This simplicity makes edge manipulations very fast.

A.2.3 Control-Flow Dependence

The **control** field points to a special kind of Node that defines the conditions under which the Node executes. These control-defining Nodes represent basic blocks in a CFG, and are described more fully in Section A.4. Here we focus on the control input itself.

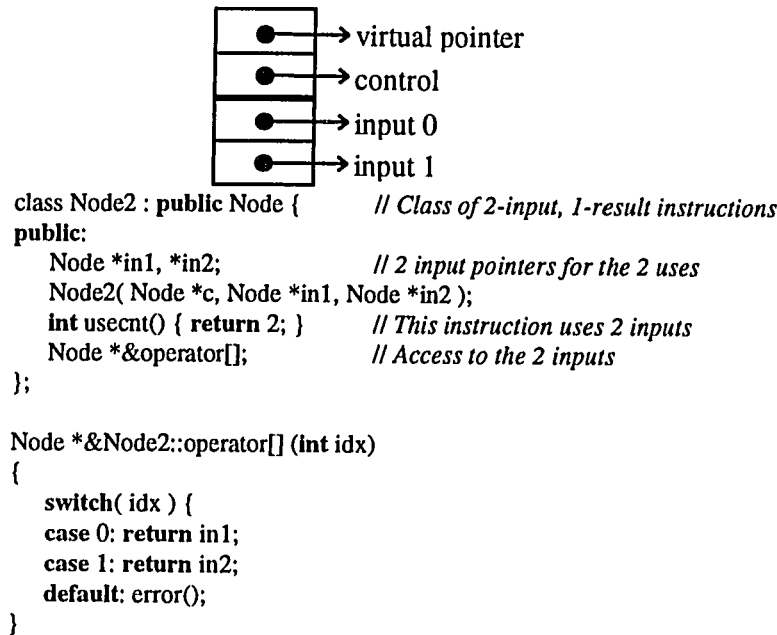

Figure A.3 Object layout and code for class Node2

Like the other inputs, the control input is a use-def edge, pointing to the basic block to which this Node belongs. Data dependences are used to serialize Nodes within the same basic block; the intermediate representation does not contain a fixed schedule. Note that basic blocks do not have any def-use pointers back to the instructions within their block. We use a simple topological sort to order Nodes in a block before printing.

A.3 Engineering Concerns

We need to handle many varieties of instructions, some require more inputs or constant fields. PHI Nodes might have any number of inputs, a NEGATE instruction has only one, and a CON instruction (which defines a simple integer constant) needs to hold the value of the constant being defined and has no other inputs. To handle all these differences we make each instruction a separate class, all inheriting from the base class Node. Figure A.4 illustrates some inherited classes.

```

class AddNode : public Node2 { // Class of Nodes that add in an algebraic ring
public:
    virtual ... // Virtual functions for different flavors of addition
};
class ConNode : public Node { // Class of Nodes that define integer constants
public:
    virtual const char *Name() { return "iLDF"; }
    int constant; // The constant so defined
};
class PhiNode : public NodeX { // Phi-functions have any number of inputs
public:
    virtual const char *Name() { return "PhiNode"; }
    virtual ...
};

```

Figure A.4 Definitions for the new Node classes

A.3.1 Virtual Support Functions

We do the local value-numbering optimization using a hash table. We hash the Nodes by opcode and inputs. The opcode is really the class virtual function table pointer, which C++ does not hand us directly. So instead we use the address of the virtual NAME() function, which is unique to each class that defines an opcode. The hash function depends on the number of inputs, so we make it virtual and define it in the base Node, Node2, Node3 and NodeX functions. To make the hash table lookup work, we must also be able to compare instructions. Differently classed instructions have different hash functions and different compare semantics. For example: addition is commutative; two ADD instructions are equal if their inputs match in any order. Code for virtual hash and compare functions is presented in Figure A.5.

```

class Node { // Base Node class
... // As before
    virtual int hash() // The no-input hash function.
    { return (int)Name+(int)control; }
}
class Node2 : public Node { // Class of 2 input, 1 result instructions
... // Previous class definition...
    virtual int hash() // 2-input hash function
    { return Node::hash()+(int)in1+(int)in2; }
};
class Node3 : public Node { // Class of 3 input, 1 result instructions
... // Previous class definition...
    virtual int hash() // 3-input hash function
    { return Node::hash()+(int)in1+(int)in2+(int)in3; }
};

```

Figure A.5 Virtual hash functions

Other common behaviors are also defined as virtual functions. In particular, algebraic identities (add of zero, multiply by 1) are handled this way. A call to the virtual `IDENTITY`, shown in Figure A.6, returns a Node equivalent to the one passed in. This same function is also used by the combined algorithm.

```

class Node {                                // Base Node class
    ...                                     // As before
    virtual Node *Identity();               // Return a pre-existing equivalent Node, if any
};
Node *IntAddNode::Identity() {              // Integer-add-specific implementation
    if( in1->Name == ConNode::Name && ((ConNode*)in1)->con == 0)
        return in1;                       // Add of a zero is just the other input
    return this;                           // Not add of a zero
}

```

Figure A.6 Virtual identity finder

A.3.2 Types and Constant Propagation

Most operations, when passed constants, produce constant results. We capture this idea with a `COMPUTE` call. `COMPUTE` looks at the operation and its inputs and determines a Node's *type*.

We treat a type as a set of values. We are interested in the set of values an instruction might take on during execution. We use a set of types arranged in a lattice. Our lattice is rich, allowing us to find ranges (with strides), simple pointers, and floating-point constants along with the usual integer constants. Figure A.7 shows the lattice structure. The double and single precision floating-point constants may be turned off with a compile-time flag.

Figure A.7 Lattice structure

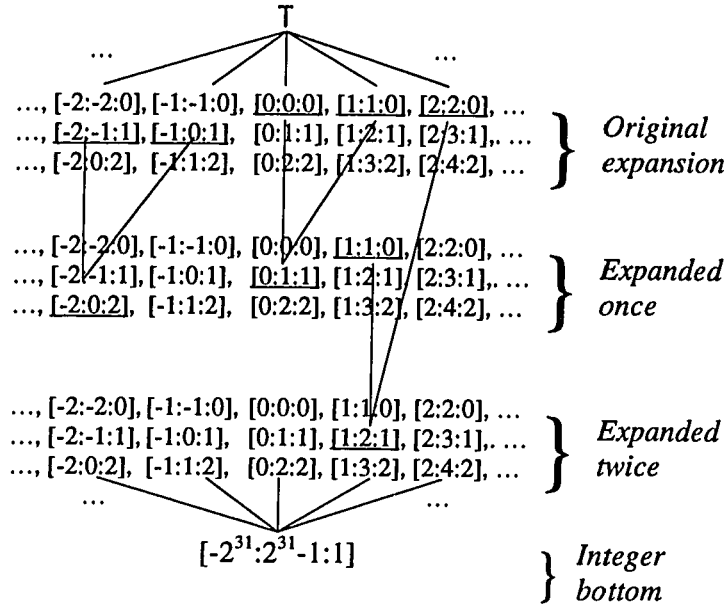

Figure A.8 Integer lattice structure

We show the integer lattice in detail in Figure A.8. The notation $[low:high:stride]$ denotes all integers between low and $high$ inclusive, stepping in units of $stride$. The $[low:high:stride]$ tuples are always kept normalized, with $stride \geq 0$, $low \leq high$, $low + stride \times k = high$ for some integer k . Each tuple is repeated once in each expansion section. The expansion sections essentially count the number of times the range has increased to include more integers. When the expansion count gets too high, the tuple falls to “integer bottom,” the tuple $[-2^{31}:2^{31}-1:1]$. Only a few lattice edges are shown.

During testing we discovered that the optimizer uses only a few types for most programs. We *hash-cons* the type objects, allowing only one instance of each unique type object. This allows for rapid equality testing (pointer equality is equivalent to structural equality). Instead of storing a type object in each Node, we store a pointer to the type object. Since there are few unique type objects they can be large and complex. Figure A.9 shows the class hierarchy for the class Type; Figure A.10 shows the corresponding C++ code.

Figure A.9 Class hierarchy for the class Type

```

class Node {                                // Basic Node class
    const Type *type;                       // Computed type for this Node
    virtual void Compute();                 // Compute a Type based on inputs
    ...                                     // As before
};
class Type {                                // Class of Type objects
    const enum TYPES basetype { // Basic type indicator
        Top, Control, I_O, Store, Float, FloatConst, Double, DoubleConst, Integer };
    // Virtual function to find the lattice meet for any two Types
    virtual const Type *meet( const Type *t ) const;
    ...                                     // Functions to hash-cons, print, etc.
};
class TypeDoubleConst : public Type {
    const double d;                        // The double precision constant
    // Virtual function to find the lattice meet; this is always a TypeDoubleConst
    virtual const Type *meet( const Type *t ) const;
    ...
};
  
```

Figure A.10 Code sample for the class Type

A.3.3 Faster Memory Allocation

Each time we make a new instruction we call the default **operator new** to get storage space. This in turn calls **malloc** and can be fairly time consuming. In addition, the peephole optimizations frequently delete a newly created object, requiring a call to **free**. We speed up these frequent operations by replacing the class specific operator **new** and **delete** for class Node. Our replacement operators use an *arena* [25]. Arenas hold heap-allocated objects with similar lifetimes. When the lifetime ends, we delete the arena freeing all the contained objects in a fast operation. The code is given in Figure A.11.

Allocation checks for sufficient room in the arena. If sufficient room is not available, another chunk of memory is added to the arena. If the object fits, the current high water mark²⁶ is returned for the object's address. The high water mark is then bumped by the

²⁶ The high water mark is the address one past the last used byte in a memory chunk.

```

class Arena {                                // Arenas are linked lists of large chunks of heap
    enum { size = 10000 };                  // Chunk size in bytes
    Arena *next;                            // Next chunk
    char bin[size];                        // This chunk
    Arena( Arena *next ) : next(next) {}    // New Arena, plug in at head of linked list
    ~Arena() { if( next ) delete next; }    // Recursively delete all chunks
};

class Node {                                // Base Node class
    static Arena *arena;                    // Arena to store instructions in
    static char *hwm, *max, *old;          // High water mark, limit in Arena
    static void grow();                     // Grow Arena size
    void *operator new( size_t x )         // Allocate a new Node of given size
    { if( hwm+x > max ) Node::grow(); old := hwm; hwm := hwm+x; return old; }
    void operator delete( void *ptr )      // Delete a Node
    { if( ptr == old ) hwm := old; }       // Check for deleting recently allocated space
    ...;                                   // Other member functions
};

Arena *Node::arena := NULL;                // No initial Arena
char *Node::hwm := NULL;                   // First allocation attempt fails
char *Node::max := NULL;                   // ... and makes initial Arena
void Node::grow()                          // Get more memory in the Arena
{
    arena := new Arena(arena);             // Grow the arena
    hwm := &arena->bin[0];                  // Update the high water mark
    max := &arena->bin[Arena::size];        // Cache the end of the chunk as well
}

```

Figure A.11 Fast allocation with arenas

object size. The common case (the object fits) amounts to an inlined test and increment of the high water marker.

Deallocation is normally a no-op (all objects are deleted at once when the arena is deleted). In our case, we check to see if we just allocated the deleted memory. If it was, the **delete** code pushes back the high water marker, reclaiming the space for the next allocation.

A.3.4 Control Flow Issues

The overall design of our intermediate representation is now clear. Each instruction is a self-contained C++ object. The object contains all the information required to determine how the instruction interacts with the program around it. The major field in an instruction is the opcode, represented as the virtual function table pointer. An object's class determines how instructions propagate constants, handle algebraic identities, and find congruences with other instructions. To make the intermediate representation understand a new

kind of operation, we need only to define a new class. The new class can inherit data fields for the instruction's inputs, and needs to supply functions for algebraic identities and hash table support. We do not need to make any changes to the peephole or value-numbering code itself. Finally, we made instruction creation and deletion very fast.

So far, we have avoided many issues concerning control, basic blocks and CFGs. Our focus has been on the instructions within a basic block. Yet control flow is an integral part of any program representation. CFGs have a two-layered structure. This two-layered structure is reflected in most analysis algorithms: the algorithm runs over the blocks of a CFG and then it does something to each block. In the next section we look at how we can remove this distinction and simplify the combined algorithm. The cost is a requirement for our global code motion algorithm.

A.4 Two Tiers to One

Our representation has two distinct levels. At the top level, the CFG contains basic blocks. At the bottom level, each basic block contains instructions. In the past, this distinction has been useful for separation of concerns. CFGs deal with control flow and basic blocks deal with data flow. We handle both kinds of dependences with the same mechanism, removing this distinction to simplify our representation.

Let us start with the instructions. Abstractly, consider each instruction to be a node in a graph. Each input to the instruction represents an edge from the defining instruction's node to this instruction's node (*i.e.*, def→use edges). The edge direction is backwards from the pointers in the instruction (*i.e.*, use→def edges). This is not a contradiction; we are defining an abstract graph. As shown in Figure A.12, the concrete implementation of this graph allows convenient traversal of an edge from sink to source (use to def) instead of from source to sink (def to use).

Every instruction has a control input from a basic block. If the control input is an edge in our abstract graph, then the basic block must be a node in the abstract graph. So we define a `REGION` instruction [21] to replace a basic block. A `REGION` instruction takes control from each predecessor block as input and produces a merged control as an output.

Figure A.12 The implementation of dependence edges

Figure A.13 shows the change from basic blocks to REGION Nodes. The control field in the base Node class points to the REGION Node defining control for the Node.

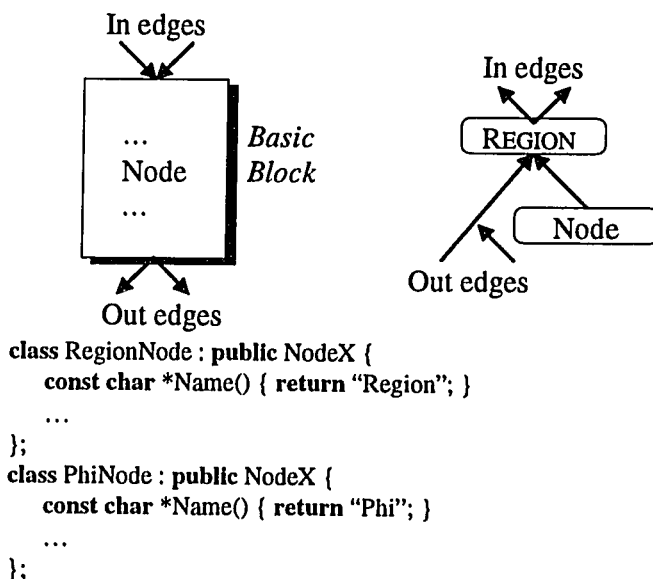

Figure A.13 Explicit control dependence

A.4.1 A Model of Execution

Having lost basic blocks and the CFG, we need to rethink our model of execution. We take our cues from the design history of the intermediate representation. Like the execution model for instructions, our model has two distinct sections. We have two distinct subgraphs embedded in our single graph representation. Optimizations make no distinction between the subgraphs; only the functions used to approximate opcodes differ. In the graph figures below, **heavy** arrows are edges that carry control and **light** arrows denote data edges.

The **control** subgraph uses a Petri net model. A single *control* token moves from node to node as execution proceeds. This reflects how a CFG works, as control moves from basic block to basic block. The model restricts the control token to existing in REGION instructions, IF instructions, and the START instruction. The Start basic block is replaced with a START instruction that produces the initial control token. Each time execution advances, the control token leaves the current instruction. The token moves onward, following the outgoing edge(s) to the next REGION or IF instruction. If the token reaches the STOP instruction, execution halts. Because we constructed the graph from a CFG, we are assured that only one suitable target instruction (REGION, IF, STOP) exists on all the current instructions' outgoing edges.

The **data** subgraph does not use token-based semantics. Data nodes' outputs are an immediate reflection of their inputs and function (opcode). There is no notion of a “data token”; this is not a Petri net. Whenever an instruction demands a value from a data instruction, it follows the use-def edge to the data instruction and reads the value stored there. In an acyclic graph, changes immediately ripple from root to leaf. When propagation of data values stabilizes, the control token moves on to the next REGION or IF instruction. We never build a graph with a loop of only data-producing nodes; every loop has either PHI or REGION Nodes.

A.4.2 Mixing the subgraphs at PHI Nodes

Our two subgraphs intermix at two distinct instruction types: PHI instructions and IF instructions. The PHI reads in both data and control, and outputs a data value. The control token is not consumed by the PHI. IF Nodes take in both control and data, and route the control token to one of two following REGION Nodes.

CFG edges determine which values are merged in the ϕ -functions. Without those CFG edges our intermediate representation is not *compositional*²⁷ [9, 39]. We need to associate with each data input to a PHI Node the control input from the corresponding basic block. Doing this directly means that PHI Nodes would have a set of pairs as inputs. One

²⁷ In essence, we would require information not local to an instruction. A non-compositional representation is difficult to transform correctly because changing an instruction may require information not directly associated with the instruction.

element of the pair would be the data dependence and the other control dependence. This is a rather ungainly structure with complicated semantics. Instead, we borrow some ideas from Ballance, *et al.* and Field [4, 22].

Our PHI Nodes inherit the required information from the underlying Node class. The control field points to the REGION Node defining control for the PHI Node. The other inputs to the PHI Node are **aligned** with the REGION Node's control inputs, as shown in Figure A.14. The i th data input to the PHI Node matches the i th control input to the REGION Node. In essence, we split the paired inputs between the PHI Node and the REGION Node.

The result computed by a PHI Node depends on both the data and the matching control input. At most one control input to the REGION Node can be active at a time. The PHI Node passes through the data value from the matching input.

Figure A.14 PHI Nodes for merging data

Note that these instructions have no run-time operation. They do not correspond to a machine instruction. They exist to mark places where values merge and are required for correct optimization. When machine code is finally generated, the PHI Nodes are folded back into normal basic blocks and CFG behavior.

A.4.3 Mixing the subgraphs at IF Nodes

If the basic block ends in a conditional instruction, we replace that instruction with an IF Node. Figure A.15 shows how an IF Node works. In the basic-block representation, the predicate sets the condition codes (the variable named *cc*) and the *branch* sends control to either block **B1** or block **B2**. With the explicit control edges, the IF Node takes both a control input and a predicate input. If the predicate is **T**, the IF Node sends control to the true basic block's REGION Node. Otherwise control is sent to the false basic block's REGION Node.

Figure A.15 An example IF construct

IF Nodes take in both a data value and the control token, and hold onto either a TRUE or a FALSE control token. This token is available to only half of the IF instruction's users, and eventually exits to only one of two possible successors. In Section A.5.1 we modify the IF instruction so that it behaves more like other control handling instructions: we give it exactly two successors, only one of which receives the control token.

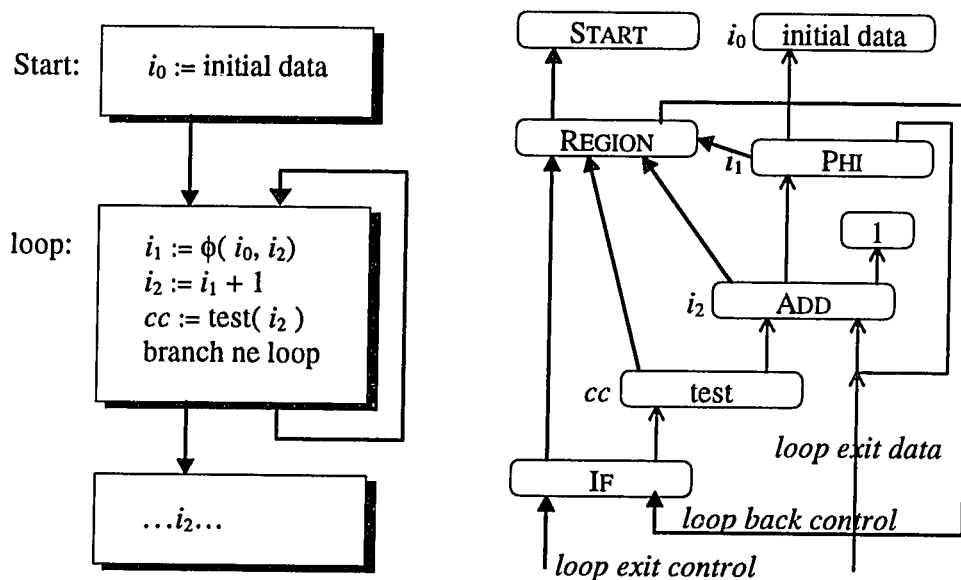

Figure A.16 An example loop

Figure A.16 shows what a simple loop looks like. Instead of a basic block heading the loop, there is a REGION instruction. The REGION instruction merges control from outside the loop with control from the loop-back edge. There is a PHI instruction merging data values from outside the loop with data values around the loop. The loop ends with an IF

instruction that takes control from the REGION at the loop head. The IF passes a true control back into the loop head and a false control outside the loop.

A.4.4 Value Numbering and Control

If we encode the control input into our value numbering's hash and key-compare functions, we no longer match two identical instructions in two different basic blocks; the function and other inputs are equal but the control input differs. We end up doing only local value numbering. Ignoring the control input (and doing some form of global value numbering) is covered in Chapter 6.

A.5 More Engineering Concerns

In the original Node-based implementation, several instruction types defined more than one value. Examples include instructions that set a condition code register along with computing a result (*i.e.*, subtract) and subroutine calls (which set at least the result register, the condition codes, and memory). Previously these instructions have been dealt with on an *ad hoc* basis. We use a more consistent approach.

Having a single instruction, such as an IF instruction, produce multiple distinct values (the true control and the false control) is problematic. When we refer to an instruction, we want to designate to a specific value. We fix this by making such multi-defining instructions produce a tuple value. Then we use PROJECTION Nodes to strip out the piece of the tuple that we want. Each PROJECTION Node takes in the tuple from the defining Node and produces a simple value. The PROJECTION Node also has a field specifying which piece of the input tuple to project out.

These PROJECTION Nodes have no run-time operation (*i.e.*, they “execute” in zero cycles). When expressed in machine code, a tuple-producing Node is a machine instruction with several results, such as a subroutine call or a subtract that computes a value and sets the condition codes. The PROJECTION Nodes, when expressed as machine code, merely give distinct names to the different results.

Computing a new Type for a PROJECTION Node is the responsibility of the tuple-producer. The Compute code for a PROJECTION Node “passes the buck” by passing the

PROJECTION on to the Compute code for the tuple-producer, letting the tuple-producer determine the PROJECTION's Type and using that result. Since non-tuple-producing Nodes should never be inputs to a PROJECTION, the default is an error as shown in Figure A.17. The Identity code is handled similarly.

```

class Node {           // Basic Node class
    // Default Type computation for projections
    virtual const Type *Compute( int field ) { abort(); }
    ...                // As before
};
class Projection : public Node {
public:
    int field;          // Specifies which slice of the tuple we want
    // "Pass the buck" - tuple-producing node computes Type for projection
    virtual void Compute() { type := control→Compute(field); }
};

```

Figure A.17 PROJECTION Nodes

A.5.1 IF Nodes

An IF Node takes in control and a predicate and produces two distinct outputs: the true control and the false control. We implement this by having the IF Node produce a tuple of those two values. Then a PROJECTION-TRUE Node strips out the true control and a PROJECTION-FALSE Node strips out the false control. The basic block that would execute on a true branch is replaced by a REGION Node that takes an input from the PROJECTION-TRUE Node. Similarly, the basic block that would execute on a false branch is replaced by a REGION Node that takes an input from the PROJECTION-FALSE Node. Figure A.18 shows both the structure of a PROJECTION Node and how it is used with an IF Node. Figure A.19 shows the code for an IF Node. In the test “control→type ≠ T_CONTROL” the use of the hash-consed Type object T_CONTROL allows us to make a structural equality test with a simple pointer comparison. T_CONTROL is a global pointer to the one Type object that defines control.

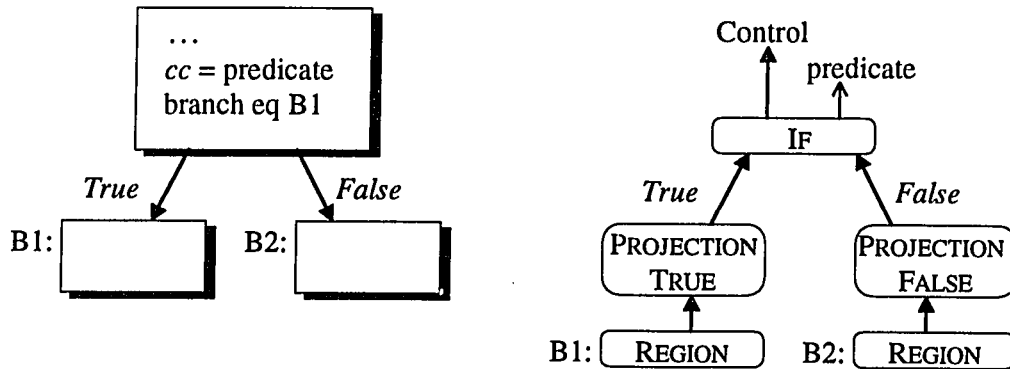

Figure A.18 Projections following an IF Node

```

public IfNode : public Node1 {           // IfNodes use control and 1 test input
    virtual const Type *Compute( int field );
};
const Type *IfNode::Compute( int field ) // Computing the type of following proj's
{
    if( control→type ≠ T_CONTROL )       // If the IfNode is not reachable then...
        return T_TOP;                   // neither is any following Proj
    if( !in1→type→is_constant() )       // If test is not a constant true/false
        return T_CONTROL;               // then assume both branches are reachable
    // If projection field matches the constant test
    // then that branch is executable (return T_CONTROL)
    // else the branch is unreachable (return T_TOP)
    return (in1→type→get_constant() = field) ? T_CONTROL : T_TOP;
}

```

Figure A.19 IF Node and optimizations

A.5.2 The START Node

The START Node needs to produce the initial control. It also needs to produce initial values for all incoming parameters, memory, and the I/O state. The START Node is a classic multi-defining instruction, producing a large tuple. Several PROJECTION Nodes strip out the various smaller values.

A.5.3 Memory and I/O

We treat memory like any other value, and call it the STORE. The START Node and a PROJECTION-STORE Node produce the initial STORE. LOAD Nodes take in a STORE and an address and produce a new value. STORE Nodes take in a STORE, an address, and a value and produce a new STORE. PHI Nodes merge the STORE like other values. Figure A.20 shows a sample treatment of the STORE.

Figure A.20 Treatment of memory (STORE)

The lack of anti-dependencies²⁸ is a two-edged sword. Between STORE's we allow LOAD Nodes to reorder. However, some valid schedules (serializations of the graph) might overlap two STOREs, requiring that all of memory be copied. Our serialization algorithm treats memory like a type of unique machine register with infinite spill cost. The algorithm schedules the code to avoid spills if possible, and for the STORE it always succeeds.

This design of the STORE is very coarse. A better design would break the global STORE up into many smaller, unrelated STORE's. Every independent variable or array would get its own STORE. Operations on the separate STORE's could proceed independently from each other. We could also add some understanding of pointers [11].

Memory-mapped I/O (*e.g.*, **volatile** in C++) is treated like memory, except that both READ and WRITE Nodes produce a new I/O state. The extra dependency (READs produce a new I/O state, while LOADs do not produce a new STORE) completely serializes I/O. At program exit, the I/O state is required. However, the STORE is not required. Non-memory-mapped I/O requires a subroutine call.

A.5.4 Subroutines

We treat subroutines like simple instructions that take in many values and return many values. Subroutines take in and return at least the control token, the STORE, and the I/O state. They also take in any input parameters, and often return a result (they already re-

²⁸ An *anti-dependence* is a dependence from a *read* to a *write*. For the STORE, an anti-dependence is from a LOAD to a STORE.

turn three other results). The peephole (and other) optimization calls can use any inter-procedural information present.

A.6 Related Work

Ferrante, Ottenstein and Warren present the *Program Dependence Graph* [21]. The PDG is more restrictive than our representation in that **control** edges are added to every node. Also, the PDG lacks the control information required at merges for an execution model. Cartwright and Felleisen extend the PDG to the *Program Representation Graph* adding value nodes to the PDG [9]. The PRG has a model of execution. Selke's thesis gives a semantic framework for the PDG [39]. The PDG has fewer restrictions than our representation where **control** edges are required. We would like to extend the combined optimization algorithm so that it understands *control dependence*.

Cytron, Ferrante, Rosen, Wegman and Zadeck describe an efficient way to build the SSA form of a program [15] which assigns only once to each variable. The SSA form is a convenient way to express all data dependences, but it also lacks control information at ϕ -functions.

Alpern, Wegman and Zadeck present the *value graph* [2]. The value graph is essentially an SSA form of the program expressed as a directed graph. The authors extend the value graph to handle structured control flow, but do not attempt to represent complete programs this way. The value graph lacks control information at ϕ -functions and therefore does not have a model of execution.

Ballance, Maccabe and Ottenstein present the *Program Dependence Web* [4]. The PDW is a combination of the PDG and SSA form and includes the necessary control information to have a model of execution. It also includes extra **control** edges that unnecessarily restrict the model of execution. The PDW includes μ and η nodes to support a demand-driven data model. Our representation supports a data-driven model and does not need these nodes. The PDW is complex to build, requiring several phases.

Pingali, Beck, Johnson, Moudgill and Stodghill present the *Dependence Flow Graph* [38]. The DFG is executable and includes the compact SSA representation of data

dependences. The DFG has switched data outputs that essentially add the same unnecessary control dependences found in the PDW. The DFG includes anti-dependence edges to manage the store; our representation does not require these. The DFG includes a denotational semantics and has the *one step Church-Rosser* property.

Paul Havlak has done some recent work on the thinned *Gated Single Assignment* form of a program [26]. This form is both executable and compact. Currently, the GSA is limited to reducible programs. The GSA can find congruences amongst DAGs of basic blocks not found using our representation. We can find congruences amongst loop invariant expressions not found using the GSA. It is not clear if the forms can be combined, or if one form is better than another. A promising implementation of thinned GSA exists and has been used on a large suite of FORTRAN applications with good results.

Weise, Crew, Ernst, and Steensgaard present the *Value Dependence Graph* [48]. The VDG is similar in spirit to our representation. It represents an independent line of research, performed in parallel with our own. Weise, et al. stress the VDG for research in partial evaluation, slicing and other optimizations; they have built visual display tools to help transformations on the VDG. We stress compilation speed and code quality; our compiler is much faster and includes a larger set of classic optimizations.

John Field gives a formal treatment of graph rewriting on a representation strongly resembling our representation. We hope to be able to use his semantics with only minimal modifications [22].

A.6.1 Summary of Related Intermediate Representations

As program representations have evolved they have gained an executable model; they include all the information necessary to execute a program. Also, restrictions on the evaluation order, expressed as edges in the graph, are lifted. The later representations are both more compact and more complete and allow more optimizations. Our representation is one more step along these lines. It has an executable model and has fewer restrictions on the evaluation order than any of the previous models. This lifting of restrictions gives analysis and optimization algorithms more freedom to discover facts and reorganize code from disjoint sections of the original program.

A.7 Summary

To produce a faster optimizer, we decided to do some of the work in the front end. We reasoned that inexpensive peephole optimizations done while parsing would reduce the size of our intermediate representation and the expense of later optimization phases. To do useful peephole optimizations we need use-def information and the static single assignment property.

We take advantage of C++'s inheritance mechanisms and structure our Nodes into separate classes for each kind of instruction. A Node's opcode is represented by the C++ virtual function table pointer. Each Node holds use-def pointers, represented as simple C++ pointers to other Nodes. We make control dependence an explicit pointer to the controlling block and make our model compositional by providing control information at PHI Nodes.

We collapse the CFG edges into the representation, just like the data edges. This is crucial to the good running time of the combined algorithm, which does not need to differentiate between the two edge types. Instead of flow analysis over the CFG edges following analysis over the data edges, we replace the two-tier CFG and basic block structure with REGION Nodes.

We use virtual functions to define opcode semantics. Constant propagation, algebraic identities and hash table behaviors are all inherited. We also use specialized allocate and delete functions. We discussed convenient mechanisms to handle instructions that defined several values, subroutines, memory, and I/O.
